LIBRARY**

VOLUME 1
Edited by Billy L. Edge

An aerial, black and white photograph of a coastal city. The city is densely packed with buildings and streets, extending to a large body of water in the foreground. The water is dark and calm. The city's layout is somewhat irregular, with buildings of various sizes and shapes. The overall scene is captured from a high angle, looking down on the city and the water.

1988 PROCEEDINGS

Twenty-first Coastal Engineering Conference

Proceedings of the International Conference
VOLUME 1

June 20-25, 1988
Costa del Sol-Malaga, Spain

Conference held under the auspices of the
Coastal Engineering Research Council of the
American Society of Civil Engineers

Organized by the Colegio de Ingenieros de
Camino, Canales y Puertos de Espana

and cosponsored by the
Directorate General for Ports and Coasts of the
Spanish Ministry of Public Works
Polytechnical Universities of
Madrid, Barcelona, Santander,
and Valencia

Edited by Billy L. Edge

Published by the
American Society of Civil Engineers
345 East 47th Street
New York, New York 10017-2398

ABSTRACT

This book contains over 220 papers presented at the 21st International Conference on Coastal Engineering. The book is divided into six parts: theoretical and observed wave characteristics; coastal processes and sediment transport; coastal structures and related problems; coastal, estuarine and environmental problems; case studies; and ship motions. The individual papers include such topics as the effects of wind, waves, storms and currents, erosion, sedimentation, and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both the theoretical and the practical, these papers provide the civil engineer with a broad range of information on coastal engineering.

The Society is not responsible for any statements made or opinions expressed in its publications.

FOREWORD

The 21st International Conference on Coastal Engineering was held in Malaga, Spain. The 21st ICCE, like the ones before it, was well organized with the primary objective being to share scientific and engineering information and to provide a forum for interaction with other engineers and scientists working similar problems. The time and efforts contributed to that objective were extensive and the results have proven that the planning is a vital part of each conference. All who attended the 21st ICCE will agree that it was a tremendous success in many ways.

Since the conference was held, Dean Morrough P. O'Brien died. Dean O'Brien has been a very familiar person to all who have attended these conferences in the past. His direction and motivation developed the International Coastal Conferences into the very successful forum we now have. For over thirty years, Dean O'Brien served as Chairman of the Council on Wave Research and subsequently the Coastal Engineering Research Council. The importance of his contributions to the Coastal Engineering profession are detailed in the "In Memorium" which is included in this volume. This volume is dedicated to Dean O'Brien for his long standing interest in coastal processes, for his dedication to development of solutions of real problems and for his untiring efforts in the development of this area of engineering.

The papers in the "Proceedings" have been prepared by the authors who made presentations at the 21st International Conference on Coastal Engineering. The authors were asked to make the presentations and submit final papers based upon review of the abstracts which were submitted well in advance of the conference. These abstracts were reviewed by a committee of four professionals active in this field, including representation from the local organizing committee. The papers included in this volume are eligible for discussion in the *Journal of the Waterway Port, Coastal, and Ocean Division* of the ASCE. All papers are eligible for ASCE awards.

Venues for the upcoming conferences are listed below:

- 22nd Delft, The Netherlands, 1990
- 23rd Venice, Italy, 1992
- 24th Kobe, Japan, 1994
- 25th USA, 1996

Countries desiring to host a future conference should contact the Secretary of the Coastal Engineering Research Council to receive information about submitting a proposal.

Billy L. Edge, Secretary
Coastal Engineering Research Council
American Society of Civil Engineers

ACKNOWLEDGMENTS

Committee of Honour

President: King Juan Carlos I

Members:

The President of the Government.
The Minister for Foreign Affairs.
The Minister for Public Works and Urbanism.
The President of the Autonomous Community of Andalusia.
The Government Representative in the Autonomous Community of Andalusia.
The Mayor of Málaga.
The Secretary of State for International Cooperation and with Ibero-America.
The Counselor for Public Works of the Autonomous Community of Andalusia.
The Civil Governor of Málaga.
The President of the Provincial Government of Málaga.
The Director General for Ports and Coasts.
The Director General of Centro de Estudios y Experimentación de Obras Públicas.
The President of Colegio Nacional de Ingenieros de Caminos, Canales Y Puertos.

Organizing Committee

President:

Dr. D. Fernando Palao Taboada.

Executive Secretary:

Prof. Dr. José Luis Juan-Aracil.

Members:

Prof. Dr. D. Felipe Martínez Martínez.
Dra. D.^a Milagros Couchoud Gregori.
Dr. D. Rafael Aznar Garrigues.
D. José Trigueros Rodrigo.

Techno-Scientific Committee

Prof. Dr. D. Pedro Suárez Bores.
Prof. Dr. D. Javier Díez González.
Prof. Dr. D. Agustín Sánchez Arcilla.
Prof. Dr. D. Miguel Losada Rodríguez.
Prof. Dr. D. José R. Medina Folgado.
Prof. Dr. D. Felipe Martínez Martínez.

Coastal Engineering Research Council

Chairman:

Prof. Robert L. Wiegel.

Vice Chairman:

Prof. Orville T. Magoon.

Secretary:

Dr. Billy L. Edge.

Members:

Prof. Eco W. Bijker.
Prof. Robert G. Dean.
Dr. Douglas N. Foster.
Prof. Kyoshi Horikawa.
Ronald M. Noble.
Thorndike Saville, Jr.
Prof. Leonardo Zeevaert.

IN MEMORIAM MORROUGH PARKER O'BRIEN

Morrrough Parker O'Brien died Thursday, the 28th of July, 1988, in Cuernavaca, Mexico. He was 85. Long the leader in coastal engineering, his wisdom and counsel will be greatly missed by all who have been privileged to work with him. He is survived by his wife Mary; a son, Morrrough, of Boulder, Colorado; and a daughter, Shiela, of Berkeley, California.

He was born in Hammond, Indiana, on 21 September, 1902. He received a B.S. in Civil Engineering from Massachusetts Institute of Technology in 1925. He did graduate work at Purdue University, 1925-27, and in 1927-28, as a Freeman Scholar, at the Technische Hochschule in Danzig and The Royal College of Engineering in Stockholm. He received three honorary degrees: the D.Sc. from Northwestern University; the D.Eng. from Purdue University; and the LL.D. from the University of California.

O'Brien engaged in three fundamentally different careers. His academic career as Professor and Dean of Engineering at the University of California, Berkeley, spanned the years 1928-59. A second career was his pioneering work in the development of coastal engineering which, while it had some impact on the research programs at Berkeley, was unrelated to his academic pursuits. His third career was his service from 1949 until his death on an annual retainer to General Electric Company.

O'Brien's academic steps were:

<i>Mechanical Engineering:</i>	
Assistant Professor	1928-31
Associate Professor	1931-36
Professor	1936-43
Chairman	1937-43
<i>Department of Engineering: Chairman</i>	1943-59
<i>Professor of Engineering:</i>	1943-59
<i>Dean, College of Engineering:</i>	1943-59
<i>Retired</i>	June 30, 1959

Ernest O. Lawrence and Robert J. Oppenheimer were appointed assistant professors in the same year as O'Brien, and the three became good friends. These associations greatly influenced his views regarding the importance of research in a modern engineering school. During his tenure as Dean of the College of Engineering at Berkeley he led the development of the College to its top-ranked status in many engineering disciplines. He was widely regarded as a powerful and perceptive leader in engineering education, understanding that modern engineering education had to be improved by a systems approach: good students are attracted to good faculty; good faculty are active in research in the outside world; good graduate students are needed to work with the faculty on research. The University furthers the interaction of students, faculty and society by the establishment of an external advisory council, and of such research units as the Institute of Traffic and Transportation Engineering

and the University-wide Water Resources Center, both of these, incidentally, begun at UC with O'Brien's help. UC President Emeritus Clark Kerr, who had served as Chancellor when O'Brien was Dean, remembered him as "the mighty Mike" and the "builder of the College of Engineering and a builder of Berkeley" during the symposium held in O'Brien's honor in March 1987 (see *Shore & Beach*, July/October 1987).

O'Brien received a number of honors from the University. O'Brien Hall, which houses the Hydraulic Laboratory and the Water Resources Center Archives, was named after him. The portrait of O'Brien reproduced with this article hangs in the entry hall of this building. He was awarded the Doctor of Laws degree. In April 1988 he was awarded the Clark Kerr Award, given by the Academic Senate to "an individual considered to have made an extraordinary and distinguished contribution to the advancement of higher education." This Award, presented by Kerr himself, was particularly notable in that it was given to O'Brien as one of four leaders "who played pivotal roles in building the academic strength of the campus." A photo of the presentation is reproduced below. Dean O'Brien was also awarded the Lamme Award for excellence in teaching by the American Society of Engineering Education.

O'Brien continued to be active in university education after his retirement from the University of California, working with Massachusetts Institute of Technology, Harvard University, and Purdue University. From 1968 on he was a part-time consultant and Professor of Coastal Engineering at the University of Florida, participating in many research projects in collaboration with Professor Robert G. Dean.

O'Brien was the founder of modern coastal engineering. He wrote a number of papers on the subject which have had a lasting influence. He was appointed Civil Engineer for the U.S. Army Board on Sand Movement and Beach Erosion in 1929, and initiated research by this board on coastal engineering. In 1930 he made field studies along the coasts of Washington, Oregon and California, and wrote a detailed seven-volume report on the results of his observations. A landmark paper on the relationship between tidal prism and entrance area was one of the results of these studies. He summarized many of his observations and thoughts on beach processes and the effects of structures on beaches in his paper "The Coast of California as a Beach Erosion Laboratory" (*Shore & Beach*, July 1936). In 1938 he was appointed a member of the Beach Erosion Board, U.S. Army Corps of Engineers, and served on it until it was abolished in 1963. He was then appointed to its successor, the Coastal Engineering Research Board, serving there from 1963 until 1978, a total of forty years on the two boards.

The years of World War II were extremely busy for O'Brien, serving as Chairman of the Mechanical Engineering Department until 1943 when he was appointed both Dean of the College of Engineering and also Chairman of the Department of Engineering. He was Executive Engineer of the Radiation Laboratory under Professor E.O. Lawrence in 1942-43. O'Brien was asked by Lawrence and General Groves, the Manhattan Project Director, to recruit an engineering team to design the production facilities at Oak Ridge for the electromagnetic system. O'Brien said that probably the most important thing he did in his life was to convince them that there was not time to build a competent staff, that they should hire companies with an established engineering staff to do the job. He was in charge of the Statewide University of California Engineering Science and Management War Training program, 1940-44, when the program registered 46,000 students who worked under 1,800

instructors. He worked for the U.S. Navy Bureau of Ships on underwater sound, on cavitation generated by submarine propellers (the results of this research were immediately implemented by submariners), and on the design and operation of amphibious craft. He also worked with Professor H.U. Sverdrup of the Scripps Institution of Oceanography on the forecasting of waves, and he directed a program of field and laboratory studies of landing craft for the Bureau.

In 1950 he and Professor Joe W. Johnson started what are now known as the International Conferences on Coastal Engineering. The first of these was held in Long Beach, California, under the auspices of the University Engineering Extension, each paper being by invitation. The most recent of these conferences was held in Torremolinos, Spain, in June 1988 when more than five hundred abstracts were submitted for consideration and fewer than half could be accommodated (O'Brien served on the Technical Papers Review Committee).

O'Brien had a strong public service orientation. He was a member of the Army Scientific Advisory Panel, 1954–65, serving as its chairman, 1961–65; a member of the Defense Science Board, 1961–65; member of the Board of the National Science Foundation (a Presidential appointment), 1958–60; and he served on numerous committees of the National Research Council.

He was active in professional societies. He was elected honorary member of the American Society of Civil Engineers (1976), the American Society of Mechanical Engineers (1979), and the Japan Society of Civil Engineers (1988). He was elected to membership in the National Academy of Engineering in 1969.

O'Brien was a leader in several fields of engineering, including pumps and air compressors. The compressor design for the first American axial flow jet engine was laid out exactly in accordance with the method presented in the paper by O'Brien and Folsom entitled "The Design of Propeller Pumps and Fans." It was incorporated in what became the J47 engine with a production run of thousands. He was elected to the General Electric Company Propulsion Hall of Fame in 1984.

In March 1987, the *Symposium to Honor Morrrough P. O'Brien—Working Solutions: Shore and Beach* was held at the University of California at Berkeley. The State University of New York at Stony Brook established the M.P. O'Brien Fellowships in 1987. The American Shore and Beach Preservation (O'Brien served as its president from 1978 to 1983) is establishing the *Morrrough P. O'Brien Award for Outstanding Achievement in Shore and Beach Preservation*.

COASTAL ENGINEERING TRENDS AND RESEARCH NEEDS

by

Robert L. Wiegel, Hon. Mem. ASCE

Abstract: The most important coastal engineering trend is the increasing demand for its application, worldwide, owing to the growing use of, and expansion of, the coastal zone. This requires research and development in: coastal zone management, including coastal erosion management; recreational use of the coastal zone; extension of coastal engineering to works in deeper water, data collection; change in relative mean sea level; construction equipment and methods; analysis, computation and hydraulic models; field experiments; waste disposal in nearshore waters; beach nourishment and detached breakwaters. The research must be expanded now. Long term funding is required, rather than the more common "start and stop" funding. Coastal engineering is one of the most difficult branches of civil engineering, as the environmental loading on structures by waves, currents and winds is always dynamic, as is the geomorphology of the beaches and nearshore regions. Furthermore, there are substantial scale effects so that full-scale field experiments are needed. It is urgent to increase the involvement of coastal engineers and scientists in meetings which include the general public, elected officials, and appointed city, county, state and federal officials and public works personnel, and to encourage interactions if better coastal works are to be designed, constructed, and operated for the public benefit.

Introduction

What is coastal engineering? In the preface to the proceedings of the first conference on coastal engineering, organized by J.W. Johnson and Morrough P. O'Brien in 1950, O'Brien states:

"A word about the term 'Coastal Engineering' is perhaps in order here. It is not a new or separate branch of engineering and there is no implication intended that a new breed of engineer, and a new society is in the making, Coastal Engineering is primarily a branch of Civil Engineering which leans heavily on the sciences of oceanography, meteorology, fluid mechanics, electronics, structural mechanics, and others. However, it is also true that the design of coastal works does involve many criteria which are foreign to other phases of civil

1 Professor Emeritus of Civil Engineering, University of California, Berkeley, California 94720. Chairman, ASCE Coastal Engineering Research Council.

engineering and the novices in this field should proceed with caution. Along the coastlines of the world, numerous engineering works in various stages of disintegration testify to the futility and wastefulness of disregarding the tremendous destructive forces of the sea. Far worse than the destruction of insubstantial coastal works has been the damage to adjacent shorelines caused by structures planned in ignorance of, and occasionally in disregard of, the shoreline processes operative in the area."

There is increasing worldwide demand for coastal engineering, owing to growing use of the coastal zone. One increasing demand is for recreation; this together with other uses, requires coastal zone management. Some uses and some areas needing research and development are (Wiegel, 1987):

- Increasing Demand for Coastal Engineering
- Recreational Use of the Coastal Zone
- Coastal Zone Management
- Extension to Works in Deeper Water
- Data Collection
- Field Experiments
- Analysis, Computation, and Hydraulic Models
- Waste Disposal in Nearshore Waters
- Beach Nourishment, Seawalls and Detached Breakwaters
- Change in Relative Mean Sea Level
- Construction Equipment and Methods

An Ad Hoc Committee for the Civil and Environmental Engineering Division of NSF, Natural Hazards and Research Needs in Coastal and Ocean Engineering, studied some of these areas and made recommendations for research in their report (1984). A committee of the National Research Council is presently assessing options for coastal erosion zone management for incorporation into the National Flood Insurance Program (NFIP) of the Federal Emergency Management Administration (FEMA). These two studies emphasize the interest in coastal engineering research needs. In addition, in the article "Restoring the Shore," by Virginia Fairweather (1987), she states:

"A recent Congressional Office of Technology Assessment report underscores the need for research on coastal solutions, concluding that 'so little is known about these natural processes (shoreline erosion) that public works improvements often are undertaken with insufficient understanding to ensure structural longevity.'"

The present paper is an update and modification of a position paper prepared by the author for use in the ASCE Conference on Civil Engineering Research Needs in the 21st. Century, held in Williamsburg, Virginia, 11-14 November 1987.

Increasing Demand for Coastal Engineering

A major reason for the increase in demand for coastal engineering is the expanding use of the coastal zone. People like to live on the coast, tourists like to visit the coast, ocean shipping is increasing, recreational uses (such as boating, bathing in the surf, walking along the shore, surfing, or just sitting on a beach) are growing, coastal fisheries are important, and there is an increasing use of nearshore waters for the disposal of large quantities of man's non-toxic wastes (including power plant waste heat and airport noise).

Another reason for the increase in demand is the developing awareness of the complexity of some problems, and the desire to do a better job. The Marine Board, National Research Council (1981), study of problems and opportunities in the design of entrances to ports and harbors is used as an example of this; it could be generalized to other activities. They state the most important problems requiring resolution to be:

- "• Improved and validated models for the prediction of horizontal and vertical ship movements in the particular conditions of harbor entrances;
- Use of systems analysis in the design of harbor entrance;
- Reliable and economical measurement, reduction, presentation, and storage of environmental data;
- Cost-effective models of the physical environment for prediction of natural conditions and forces, and changes caused by human activity;
- Improved procedures for prediction of shoaling rates and patterns, including development and verification of appropriate field methodologies;
- Improved entrance-channel design and operating criteria;
- Development of accepted standards and uniform methods for measuring and assessing navigability of harbor entrances;
- Quantitative definition of the needs of mariners;
- Review and reform of decision making processes for port and harbor projects, and
- Evaluation of the importance of natural resources for balanced decisions about harbor siting and related matters, and increased attention to the restoration of natural habitats."

Nearly 500 million yd³ of material are dredged each year in the U.S.A. to create and maintain navigable waterways and harbors (National Research Council, Marine Board, 1987). Alternatives to dredging will be a major opportunity in the 21st century. The 1987 Marine Board report on sedimentation control concludes that each harbor, channel and turning basin is unique, and must be studied and treated separately, investigating 3 options: 1) stopping the sediment before it reaches the site; 2) keeping the material in suspension as it passes through the site; 3) diverting the sediment flow away from the site.

The relationship between coastal engineering and port engineering is close, and one should consider how trends in port engineering affect coastal engineering, and vice versa. As pointed out in a recent PIANC Working Group report (1986), the traditional freighter has almost disappeared from the seas, with a substantial amount of the replacement being by very large container and roll-on/roll-off ships. These often require deeper navigation channels, and major changes in shoreside arrangements. Redevelopment of urban waterfronts results, often with emphasis on needs for recreation and tourists; interest in this is such that there is now an annual conference in the U.S.A. on "Urban Waterfronts." These factors result in more demand for coastal engineering and coastal zone management.

Recreational Use of the Coastal Zone

In southern California, the attendance in 1984 at state, county and city beaches was approximately 126.5 million (POD, 1985). About 43 million tourists visited Spain in 1985, most of whom spent all, or part of their time on the coast. It has been estimated that in Japan the use of beaches would increase from 110 million in 1975 to 220 million by 1990 (Nakayama et al., 1982). Rockaway Beach, on the Atlantic Coast of New York City, has an estimated 24 million "annual uses" (Nersesian, 1977). About 30 million tourists visit Florida each year, with most of them making use of the state's beaches (Wiegel, 1988). In some areas, tourists visiting beaches are responsible for a major segment of local jobs and income, and some countries are trying to increase tourist use of their coasts. For the general benefit of the world's economy, and the well-being of its people, it is necessary for highly industrialized countries to shift some emphasis from internal industrial production to the recreational use of coasts in other countries, and in doing so, transfer to them funds that are required for their development.

One trend that will continue into the 21st century, derivative of recreational use, is increasing use of beach nourishment; this is considered in a separate section. Another trend is the construction of outfall sewers into deeper water, farther seaward of beaches. An example is the outfall sewer for Honolulu, Hawaii, which together with an advanced primary treatment plant, "has completely cleaned up nearshore pollution, and no longer threaten beach areas" (Miyamira et al., 1979).

Growth of recreational boating is substantial, and the shortage of small boat harbors and/or marinas is often the limiting factor in the expansion of boating. Often these require the construction of breakwaters or jetties, which affect the contiguous coast.

Coastal Zone Management, Including Coastal Erosion Control Management

One factor mentioned by O'Brien, damage to adjacent shorelines caused on occasions by structures constructed for other purposes, is one of the reasons for the trend in the increasing use of coastal zone management; its growth is phenomenal (Wiegel, 1987). In the 1970's, the U.S. Congress passed the Coastal Zone Management Act, a national policy "to preserve, protect, develop, and where possible, to restore or enhance, the resources of the Nation's coastal zone for this and succeeding generations." As a result, many coastal states developed coastal management plans.

An important part of coastal zone management is public education, and this is done successfully in different ways, on different scales. One example is the conference "Beach Erosion, A Regional Alternative," held in Santa Barbara, California on 24-26 October 1985. It was sponsored and organized by the California Chapter of the American Shore and Beach Preservation Association and the Santa Barbara-Ventura County Erosion Control Group. Presentations were made by engineers, scientists, lawyers, planners, elected and appointed city, county and state officials and legislators. Another example is the symposium "Beach Preservation Technology 88: Problems and Advancements in Beach Nourishment," in Gainesville, Florida on 24-25 March 1988, arranged by the Florida Shore & Beach Preservation Association, in which there was a similar mix of backgrounds. Many of the general public attended, and participated in both of these meetings. This type of activity must be expanded.

Other countries have coastal zone management plans and agencies. The Queensland, Australia, Beach Protection Authority was established in 1968, with the legislation changed substantially in 1984 (QBPA, 1985). The Authority "...deals with management of the whole of the Queensland coast and its main function is to provide advice to Local Authorities, Harbour Boards and River Improvement Trusts which are responsible for implementing coastal management programmes, whether these programmes relate to beaches, rock foreshores, sand flats, estuaries or river banks in tidal areas."

Japan, in 1956, enacted their Coastal Law, and they have implemented three 5-year Seashore Protection Projects (1st. 5-year plan, 1970-74; 2nd 5-year plan, 1976-80; 3rd. 5-year plan, 1981-85) (Nakayama et al., 1982). Japan has 34,000 km of coast, with about 16,000 km requiring protection of which almost 8,700 km is already protected by seawalls, etc. Denmark has a shore protection plan. Other countries are developing national coastal erosion management plans. Egypt is developing a plan for the Nile Delta, which is eroding considerably along much of its boundary with the Mediterranean Sea (Diephuis et al., 1983). The plan has been prepared under the Shore Protection Authority of Egypt, with the cooperation of the UNDP (Kadib et al., 1986). Malaysia completed their national coastal erosion study in 1986; it will be a major input to their coastal zone management plan (Nathan and McAlister, 1987). Sri Lanka is working on a plan (Amarasinghe et al., 1987).

Extension of Coastal Engineering to Works in Deeper Water

Economies of deep draft bulk carriers has led to more dredging in many ports, to building artificial harbors in relatively deep water, and to offshore terminals.

A serious problem occurred in breakwaters in deep water, subjected to large waves, which used large concrete armor units. As pointed out by O'Brien, the internal stresses in the units increase with size (weight/cross-sectional area $W/L^2 = D$), so there is little reserve strength in large units, and extensive failures occurred (Godden, 1981; Edge et al., 1982). Engineers are studying how to improve our ability to design and construct better breakwaters in deep water at exposed locations, both rubblemound and caisson types; this must be accelerated.

The disposal of wastes using outfalls constructed farther offshore into deeper water is growing. An outfall extending into water 240 feet deep was built offshore Honolulu, Hawaii (Miyamira et al., 1979). The recently completed San Francisco outfall (Murphy and Eisenberg, 1985), extends 23,400 feet offshore, into water 80 feet deep, with a capacity of 450 million gallons per day. It crosses one of the world's major active earthquake fault zones, the San Andreas. A similar ocean outfall is being planned for Taipei, R.O.C. The submarine siphons for the ocean disposal system of the Athens, Greece, sewerage system have recently been completed, and this is also in a semically active region (Eisenberg et al., 1988). Research is needed on the design of ballast for such pipelines.

Data Collection

Long-term management plans should be based on, or incorporate provisions for detailed studies of extended regions, which include data collection and analysis. This is being done in Queensland, Australia, and in Japan. Egypt is studying the Nile Delta, which is eroding owing to the shortage of sediment supplied to the coast by the Nile River due to the Aswan High Dam and the low dams located a few miles upstream from each of the two mouths of the Nile. As the transport of sand is in an easterly direction along the southeastern coast of the Mediterranean Sea, from Alexandria, past Sinai, to Haifa, Israel, the effects are extensive. Field studies have been made, and are being made of the waves, currents, sediment characteristics, beach profiles, sediment transport, etc., along the Nile Delta as an input to their plan. Terms of reference for the development of a plan for the Nile Delta was prepared by Diephaus, Mobarek, Saville and Wiegel (1983). The recommended work has been completed, and a report made to the Egyptian Government (Kadib et al., 1987). In California, the US Army Corps of Engineers (Los Angeles District, 1983) is making a long-term study "...to provide coastal data and information to planners and decision-makers so that better and more informed decisions can be made regarding the restoration and maintenance of the 1,100-mile California coastline."

Although the number of wave measuring programs is increasing, almost no measurements are being made routinely of surf and nearshore currents, and almost no measurements are being made of directional spectra; these data are needed, and must be long term to provide an adequate time series for statistical analysis. Hindcast wave data are used to supplement measurements, or as a substitute for measurements if not available. Weather data, available from about 1900, can be used as input. This type of work should be expanded.

There is much interest in making measurements in the ocean. In April 1986 the International Conference on Measuring Techniques of Hydraulic Phenomena in Offshore, Coastal & Inland Waters was held in England. It was concluded that better methods of making routine measurements for coastal engineering use must be developed. Presently the Marine Board, National Research Council, has a Committee on Coastal Engineering Measurement Systems to assess operational needs and research requirements for making coastal measurements for engineering purposes.

Field Experiments

The trend to conducting field experiments is slow, owing to their high costs. Examples of three experiments are: 1) Oceanside, CA, sand bypassing system (Diemer, 1987); 2) Crescent City, CA, instrumented 42-ton dolos concrete armor units (Kendall et al., 1986; Wood et al., 1986); 3) floating breakwater, Friday Harbor, WA (England, 1986). The performance of comprehensive field experiments must be expanded, such as the wave, current and beach 1980 ARSLOE and 1986 SUPERDUCK experiments at Duck, NC, and the thermal power plant coastal cooling water tests reported by Wiegel and Doyle (1987).

Many citations are given to the 'Bruun Rule.' The author has always had misgivings about this rule, as there are examples of sand moving from offshore onto beaches (for a recent study, see Williams and Meisburger, 1987). Dean (1987) has reexamined this 'rule,' and concludes that there are conditions under which sand will move onto beaches. Field studies of this problem must be made.

Analysis, Computation and Hydraulic Models

A major trend in coastal engineering is the continuing development of our ability to analyse problems in the sciences mentioned in O'Brien's statement on coastal engineering, including growth in the use of computers to obtain numerical solutions. Great advances have been made in our capabilities to analyse problems using analytical and numerical techniques, but there is still need for hydraulic models to check theory, and to study coastal projects in which the details are very complicated (see, for example, Wiegel and Doyle, 1987).

Waste Disposal in Nearshore Water

Nearshore ocean water is a convenient sink for the disposal of non-toxic wastes. In many coastal locations untreated wastes flow into the ocean, at a very low cost. This is no longer permitted in many locations, and the trend, sometimes an over-reaction, is to expensive outfalls extending perhaps more than four miles offshore into water as much as 200 feet deep. Treatment plants may be a part of the system. Research is being done on mixing processes of buoyant fluid discharge in the ocean, and on environmental conditions. A few references have already been given to major ocean outfall installations. Studies of the effect of effluent discharged into the nearshore waters are of great importance in the planning of ocean outfalls. The most extensive and long-term study of the effects of municipal waste discharge on marine life and human health is being done off southern California (Bascom, 1984); a long-term study of the disposal of waste heat in a local region, is described by Wiegel and Doyle (1987). These types of studies are needed for other regions.

Beach Nourishment, Seawalls and Detached Breakwaters

With increasing recreational use of beaches, there is a trend to the placement of sand on beaches in erosional areas, and also in some areas where no beaches exist. Sand bypassing at harbor entrances is an example. Since construction of the

jetties at the entrance of small boat harbor at Santa Cruz, California, sand has accumulated upcoast from the west jetty. This protects bluffs that were eroding badly before the construction, and buildings on the bluffs. The sand trapped upcoast and in the harbor entrance was not moving downcoast. The entrance became unusable, and had to be dredged, with the sand being deposited downcoast, to nourish those beaches. Similar conditions exist at Santa Barbara and at Oxnard, California, at Durban, South Africa, at Carrara, Italy, and at other sites. Sand bypassing and beach nourishment is a well-established coastal erosion management tool, and its use should increase in the next century. A little of the history of the subject, together with some conceptual and design considerations, and recommendations for needed research was presented by the author (Wiegel, 1988) at a recent symposium on this subject. It is very clear from existing studies that we should not waste sand in harbor dredging projects by dumping it in deep water. The importance of the detrimental effect of dumping sand in water too deep for it to be moved onto a beach by natural processes can be illustrated by a calculation by Dean (1988). He estimates that on the east coast of Florida more than 40 million cubic meters of sand have been dumped in deep water. Assuming an average simplified beach profile extending to offshore "closure", he calculated that this quantity is the equivalent of an additional 8 meters of beach width along the entire 640 km length of the east coast of Florida.

A symposium on beach nourishment was held in Gainesville, Florida on 24-25 March 1988, sponsored by the Florida Shore & Beach Preservation Association, the proceedings of which will be published. This has been referred as earlier in the present paper.

In high population density coastal areas it can be economical to dredge sand from offshore, from harbor entrances, from inshore regions, and place it on the shore to build a wide beach. Examples are Miami Beach, Florida (10.5 miles of beach, with 14 million yd³ of sand placed, by 1980, for \$64 million); Rockaway Beach, New York (completed in late 1977, 6.2 miles of beach, about 6-2/3 million yd³ of sand placed, for about \$14.3 million); Waikiki, Hawaii; 8.5 million cubic meters dredged from offshore and placed along 8 km of beach near Zeebrugge, Belgium; Durban, South Africa; Singapore; 141,000 cubic meters at Walland, England with 31,000 cubic meters annual replenishment; Gold Coast, Queensland, Australia (2.4 million cubic meters). Beach nourishment in Japan is extensive. About 108 million yd³ in about 60 different projects was placed in southern California between 1919 and 1978 (Herron, 1980). A new look is needed of the economics of using large bulk carriers to transport sand from relatively distant sources to densely populated areas where the value of beaches is great.

In a recent study of four large volume beach nourishment projects, Egense and Sonu (1987) conclude:

"At the present stage of technology, beach nourishment is more art than science. Although many uncertainties continue to characterize the design and construction procedures, opportunities for establishing rational guidelines appear available from careful re-analysis of past and on-going projects. The importance of implementing comprehensive, long-term monitoring programs and performing more in-depth comparative studies cannot be over emphasized".

"As a general guideline within the limited scope of this study, it can be stated that compartmentalization of a project beach has the single most important effect on the retention of the placed fill. It may be about time to question the wisdom of using beach nourishment without additional measures to enhance fill retention on beaches that have little or no compartmentalization".

Detailed monitoring of beach nourishment projects is needed. Chapman (1980) reports on the monitoring of a 2.4 million m³ project at Gold Coast, Australia. Over 400 profiles were measured from the backshore to a point of zero change in the inshore zone, and 38 tons of tracer was injected into the dredge line at a controlled rate. They found that the sand moved in slugs and there was poor correlation between the subaerial beach width and the sand prism volume, including the inshore region. This is an example of what is needed by coastal engineers to improve their capability to design this type of project.

Much misinformation is spoken and written about how seawalls and revetments function. The statement is often made that they "cause beach erosion." This is unproven at best, and wrong at worst. Very few people build seawalls unless their property is already subject to erosion. The seawall is blamed for the erosion which occurs in an already eroding location (O'Brien and Johnson, 1980; Wiegel, 1987). Prior to making a decision on whether or not to use a seawall, the papers of Krauss (1987), Dean (1986; 1988), and Grigg and Tait (1987) should be studied. More field studies should be made of the effects, if any, of seawalls not normally exposed to wave action.

In some places the use of a seawall or revetment, constructed between the nourishment project and the buildings and infrastructure, should be considered as backup protection during a particularly severe winter in which much of the sand may be moved offshore or alongshore. The structure can be covered by sand, with dune grass and other vegetation planted in the sand (Wiegel, 1988).

Detached breakwaters for coastal protection are used extensively in some countries and their use is growing. More than 2,300 detached breakwaters are in Japan; the number grew exponentially between 1962 and 1982 (from 205 to 2,305) (Toyoshima, 1982). The writer has looked at many detached breakwaters in Italy, Monaco, Spain, Singapore, Israel, and the USA. Many have functioned well, but they sometimes cause erosion downcoast if there is a net littoral drift. In some circumstances they may fill too much, causing other problems. They are an excellent coastal erosion control tool, but their design requires a detailed site study of waves, currents, sediment supply, and sediment transport.

Change in Relative Mean Sea Level

A change in relative mean sea level is expected in the next century, owing to rising eustatic mean sea level (resulting partly from the "greenhouse effect"), land subsidence from both geophysical and human activity, and other processes. These changes would require major coastal engineering work. Much information useful to coastal engineers is in the report of the U.S. National Research Council Marine Board's Committee on Engineering Implications of Changes in Relative Mean Sea Level (1987). Two of their recommendations are:

"The committee concluded that the most appropriate present engineering strategy is not to adopt one particular sea level rise scenario, but instead to be aware of the probability of increasing sea level and to keep all response options open. In many engineering projects, it may be desirable to carry out sensitivity calculations, using specific sea level rise scenarios. If a particular structure is ill-suited for retrofitting, it will undoubtedly be appropriate to allow for an acceleration of sea level rise in the initial design. Sea level change during a structure's design service life should be considered along with other factors, but a change does not present such essentially new problems as to require new techniques of analysis."

"The committee's recommendations highlight the need for continuing and increased scientific study of the rates and causes of sea level change and the development of a sound basis for forecasting these changes. Efforts to understand coastal processes and the effects of sea level rise on engineering projects should also be expanded considerably."

Construction Equipment and Methods

There has been a great advance in our ability to construct and install large complex structures in deeper water farther offshore than previously. The value of offshore oil and gas in the 1970's and early 1980's was so huge that considerable money was made available to engineers for developing this capability. Equipment is available which can work in the open sea, together with well-trained experienced people to operate them (Gerwick, 1986). Much of this equipment can be used for the construction of coastal engineering works, such as pipelines for disposal in the ocean of non-toxic wastes (municipal wastes, power plant cooling water), breakwaters for deep water ports, offshore special purpose terminals, manmade islands for airports and industrial facilities, beach nourishment projects, and marinas.

CHAPTER 1

NONLINEAR DIFFRACTION BY A VERTICAL CYLINDER

David L. Kriebel *

ABSTRACT

A theoretical solution is developed for the interaction of second-order Stokes waves with a large vertical circular cylinder in water of finite depth. The solution is obtained in terms of the velocity potential such that any kinematic or dynamic quantity of interest may be derived, consistent to the second perturbation order. In this study, the second-order wave field around the cylinder is determined, showing the modification of the incident Stokes waves by wave-wave and wave-structure interactions, both in the reflection-dominated up-wave region and in the diffraction-dominated down-wave region. The theory is then compared to experimental data for wave runup and rundown amplitudes on the cylinder as well as for wave crest and trough envelopes in the up-wave and down-wave regions.

INTRODUCTION

Over the past 15 years, numerous theories have been proposed for the problem of the interaction of second-order Stokes waves with a fixed vertical circular cylinder. The first-order problem - the linear diffraction theory - was solved by MacCamy and Fuchs (1954); however, the second-order problem has proven more difficult to solve and, at present, none of the proposed solution is universally accepted. A review of all previous theories for the nonlinear diffraction problem is beyond the scope of this paper. Some of the most recent second-order diffraction theories for a vertical cylinder include those of Chen and Hudspeth (1982), Hunt and Williams (1982), Rahman and Heaps (1983), and Sabuncu and Gören (1985), while Garrison (1978) presents a nonlinear diffraction theory for arbitrary fixed or floating bodies.

The goals of this paper are to review a theory for the second-order diffraction problem developed recently by the author and to present examples of the resulting second-order free surface and nonlinear wave runup. These features of the nonlinear free surface are found to differ significantly from the linear solution, unlike the second-order wave forces which most theories predict are only slightly larger than the forces derived from linear diffraction theory. Interestingly, few of the previous theories have considered second-order free surface features, despite the fact that the second-order free surface contains fundamental nonlinear effects for a very simple geometry that has been widely used in offshore construction.

* Ocean Engineering Program, United States Naval Academy, Annapolis, MD 21402

THEORETICAL DEVELOPMENT

The problem under consideration consists of a fixed, vertical cylinder of radius, a , in water of uniform depth, d , subjected to nonlinear periodic waves of height, H , propagating in the positive x direction as shown in Figure 1. It is assumed that the fluid is irrotational and incompressible such that a potential-flow solution may be obtained in terms of the velocity potential, $\Phi(r, \theta, z, t)$. This potential must then satisfy the Laplace equation plus appropriate kinematic and dynamic boundary conditions at the bottom, at the free surface, at the cylinder, and in the far field.

Figure 1. Definition sketch.

Due to the complexity of the nonlinear boundary value problem, an approximate solution is sought through a perturbation expansion in which the velocity potential and the free surface elevation are expressed in series form as

$$\begin{aligned}\Phi &= \Phi_1 + \Phi_2 + \dots \\ \eta &= \eta_1 + \eta_2 + \dots\end{aligned}\quad (1)$$

where the first-order term has a linear dependence on the wave steepness, kH , while the second-order term has a dependence like $(kH)^2$, where k is the linear wavenumber. In addition, the free surface boundary conditions are expanded in a Taylor series about the still water level, $z = 0$. As a result, separate boundary value problems are obtained for each term in the perturbation expansion, Φ_1 and Φ_2 .

At first-order, the solution must be obtained for the linear boundary value problem, which may be expressed as

$$\nabla^2 \Phi_1 = 0 \quad (2a)$$

$$\Phi_{1z} = 0 \quad \text{on } z = -d \quad (2b)$$

$$\Phi_{1tt} + g\Phi_{1z} = 0 \quad \text{on } z = 0 \quad (2c)$$

$$\Phi_{1r} = 0 \quad \text{on } r = a \quad (2d)$$

$$\lim_{r \rightarrow \infty} r^{1/2} (\Phi_{1r}^* - ik\Phi_1^*) = 0 \quad (2e)$$

where the combined free surface boundary condition, (2c), is particularly important since it governs the wavenumbers of the linear solution and since it changes dramatically at second-order. The general solution for this linear diffraction problem has been given by MacCamy and Fuchs (1954) as the real part of

$$\Phi_1 = -\frac{igH}{2\sigma} \frac{\cosh k(d+z)}{\cosh kd} \sum_{n=0}^{\infty} \beta_n \left[J_n(kr) - \frac{J'_n(ka)}{H'_n(ka)} H_n(kr) \right] \cos n\theta e^{-i\sigma t} \quad (3)$$

where $\beta_n = (2 - \delta_{n0}) i^n$ and where δ_{n0} is the Kronecker delta function. In (3), the infinite series of Bessel functions $J_n(kr)$ represents linear incident plane waves while the Hankel functions $H_n(kr)$ represent outwardly-propagating linear scattered waves.

At second-order, the governing boundary value problem is considerably more complicated due to nonlinear forcing terms which appear in the free surface boundary condition. The second-order boundary value problem may be given by

$$\nabla^2 \Phi_2 = 0 \quad (4a)$$

$$\Phi_{2z} = 0 \quad \text{on } z = -d \quad (4b)$$

$$\Phi_{2tt} + g\Phi_{2z} = \frac{1}{g} \Phi_{1t} [\Phi_{1ttz} + g\Phi_{1zz}] \quad (4c)$$

$$-2 \left[\Phi_{1r} \Phi_{1rt} + \frac{1}{r^2} \Phi_{1\theta} \Phi_{1\theta t} + \Phi_{1z} \Phi_{1zt} \right] \quad \text{on } z = 0$$

$$\Phi_{2r} = 0 \quad \text{on } r = a \quad (4d)$$

and a form of the radiation condition, which is not well-posed for the second order problem. Because of the quadratic forcing terms on the right side of (4c), the second-order boundary value problem is nonhomogeneous. The second-order solution is therefore expected to have both particular solutions, which represent forced wave motions due to nonlinearity in the free surface boundary condition, as well as complementary or homogeneous solutions, which represent free scattered wave motions at second-order.

By substituting the first-order solution in (3) into the second-order free surface boundary condition in (4c), it is found that the quadratic forcing is periodic and oscillates at twice the frequency of the linear waves. The quadratic forcing is also an even function of θ , such that (4c) may be rewritten in series form as

$$\Phi_{2tt} + g\Phi_{2z} = -i \frac{(gkH)^2}{8\sigma} \sum_{n=0}^{\infty} [f_n^{II}(r) + f_n^{IS}(r) + f_n^{SS}(r)] \cos n\theta e^{-i2\sigma t} \quad (5)$$

Expressions for the radial functions $f_n^{II}(r)$, $f_n^{IS}(r)$, and $f_n^{SS}(r)$ are given by Hunt and Williams (1982), Sabuncu and Gören (1985), or Kriebel (1987), where each term represents a distinct nonlinear product term from the first order incident and scattered waves.

In (5), the f_n^{II} term represents plane-wave forcing which leads to the expected second-order plane-wave component at wavenumber $2k$, as found in the usual Stokes second-order wave theory. This term would exist at second-order even if no cylinder were present and is the result of nonlinear self-interactions of the first-order incident waves. The remaining forcing terms, f_n^{IS} and f_n^{SS} , are the result of nonlinear cross-interactions of the first-order incident and scattered waves and nonlinear self-interactions of the first-order scattered waves, respectively. These forcing terms behave much like a non-uniform pressure field applied to the free surface and they generate additional cylindrical standing and outwardly progressive waves at second-order.

The solution for the second-order velocity potential may be obtained by separating the potential Φ_2 into particular solutions, Φ_2^P , and complementary or homogeneous solutions, Φ_2^H , as

$$\Phi_2 = \Phi_2^P + \Phi_2^H \quad (6)$$

Based on (5), the particular solution may be further separated as

$$\Phi_2^P = \Phi_{2P}^{II} + \Phi_{2P}^{IS} + \Phi_{2P}^{SS} \quad (7)$$

The component, Φ_{2P}^{II} , then represents the forced wave motion generated by the f_n^{II} forcing, which is the usual Stokes plane wave component given by the real part of

$$\Phi_{2P}^{II} = -i \frac{3g(kH)^2}{8\sigma} \frac{(\tanh^2 kd - 1)}{(2k \tanh 2kd - k_2 \tanh k_2d)} \frac{\cosh 2k(d+z)}{\cosh 2kd} \sum_{n=0}^{\infty} \beta_n J_n(2kr) \cos n\theta e^{-i2\sigma t} \quad (8)$$

The wavenumber k_2 is the characteristic free wavenumber for the second-order problem and satisfies the second-order dispersion relationship

$$4\sigma^2 = gk_2 \tanh k_2d \quad (9)$$

which can be obtained from the homogeneous form of the free surface boundary condition in (4c) or (5). It is found that k_2 approaches $4k$ in deep water but approaches $2k$ in shallow water, where Φ_{2P}^{II} becomes infinite due to resonant forcing in the free surface boundary condition, as is well known.

In the same way, other forced wave components exist in the "incident" wave field due to the remaining f_n^{IS} and f_n^{SS} forcing terms. The solution for these second-order forced waves is found in closed integral form based on a source distribution method, which may be formalized by application of either Green's theorem or through use of Hankel transforms. In this analysis, the solution is first obtained for an isolated point source of pressure oscillating on the free surface. This result is then generalized by integrating over the free surface in r and θ , to account for the distribution of the actual quadratic forcing found in the second-order free surface boundary condition. The solution follows that of Wehausen and Laitone (1960) for an arbitrary pressure distribution on the free surface; and, the resulting velocity potential due to the distributed forcing terms, f_n^{IS} and f_n^{SS} , may be shown to be given by

$$\begin{aligned} \Phi_{2P}^{IS} + \Phi_{2P}^{SS} = & -i \frac{g(kH)^2}{8\sigma k} \sum_{n=0}^{\infty} \cos n\theta \left[i2\pi \frac{k_2 \cosh k_2d \cosh k_2(d+z)}{k \sinh 2k_2d + 2k_2d} J_n(k_2r) D_n(k_2) \right. \\ & \left. + PV \int_0^{\infty} \frac{\kappa \cosh \kappa(d+z)}{k \cosh \kappa d (\kappa \tanh \kappa d - k_2 \tanh k_2d)} J_n(\kappa r) D_n(\kappa) d\kappa \right] e^{-i2\sigma t} \end{aligned} \quad (10)$$

where "PV" represents a Principal Value integral and where $D_n(\kappa)$ represents a wavenumber spectrum for cylindrical wave motions based on a Hankel transform as

$$D_n(\kappa) = \int_a^\infty r' [f_n^{IS}(r') + f_n^{SS}(r')] J_n(\kappa r') dr' \quad (11)$$

In the solution given by (10), the principal value integral represents standing wave motions based on a continuum of wavenumbers that are required to fit the complicated free surface boundary condition arising from the quadratic forcing. Away from the cylinder, however, only the second-order free wavenumber, k_2 , is important and the integral term yields a cylindrical standing wave in the far field. From the source distribution method, the wave motions generated by any point source must satisfy the Sommerfeld radiation condition and yield outwardly propagating wave motions far from each source. Therefore, the additional term in the solution (10), represented by the component containing $J_n(k_2 r)$, is required so that the entire solution satisfies a form of the radiation condition.

The complicated forced-radiated waves given in (10), together with the incident bound second-harmonic given in (8), satisfy the nonlinear free surface boundary condition but do not satisfy the no-flow condition on the cylinder boundary by themselves. By allowing these waves to interact with the cylinder, second-order scattered waves must exist which are given by the complementary or homogeneous solutions in (6). These solutions must satisfy the Laplace equation, the bottom boundary condition, the Sommerfeld radiation condition, and the homogeneous form of the free surface boundary condition; and, they may be found from the general set of eigenfunction solutions for cylindrical waves as given by Dean and Dalrymple (1984) as

$$\begin{aligned} \Phi_2^H = & \sum_{n=0} a_{n0} \cosh k_2(d+z) H_n(k_2 r) \cos n\theta \\ & + \sum_{n=0} \sum_{j=1} a_{nj} \cos \kappa_{2j}(d+z) K_n(\kappa_{2j} r) \cos n\theta e^{-i2\sigma t} \end{aligned} \quad (12)$$

From the homogeneous form of the second-order free surface boundary condition, two second-order dispersion relationships result which specify the wavenumbers k_2 and κ_{2j} . For outwardly propagating second-order free waves

$$4\sigma^2 = gk_2 \tanh k_2 d \quad (13)$$

which was given in (9); while for the standing or evanescent wave modes, the wavenumbers are given by

$$4\sigma^2 = -g\kappa_{2j} \tan \kappa_{2j} d \quad (14)$$

which has infinitely many positive roots, κ_{2j} , given by

$$(j - \frac{1}{2})\pi \leq \kappa_{2j} h \leq j\pi$$

The homogeneous solutions therefore consist of outwardly radiating second-order free waves as well as local standing waves, i.e. evanescent modes, both of which are determined to within a set of unknown constants. The unknown coefficients, a_{n0} and a_{nj} , are then determined by satisfying the no-flow condition on the cylinder. This is accomplished with the same procedure that is used to obtain the first-order scattered wave solution, based on the orthogonality properties of $\cosh k_2(d+z)$ and $\cos \kappa_{2j}(d+z)$. The method is straightforward but lengthy; thus, it will not be given in detail in this paper.

The final solution at second-order is completely specified by combining the particular solutions in (8) and (10) with the complementary solutions obtained from (12) after evaluating the unknown coefficients. The solution for the second-order velocity potential is derived in detail by Kriebel (1987) and may ultimately be expressed in closed integral form as

$$\begin{aligned}
 \Phi_2 = & -i \frac{g(kH)^2}{2k\sigma} \sum_{n=0}^{\infty} \cos n\theta \\
 & \cdot \left[C_1 \cosh 2k(d+z)\beta_n J_n(2kr) - C_{10} C_0 \cosh k_2(d+z)\beta_n \frac{J'_n(2ka)}{H'_n(k_2a)} H_n(k_2r) \right. \\
 & \quad \left. - \sum_{j=1}^{\infty} C_{1j} C_j \cos \kappa_{2j}(d+z)\beta_n \frac{J'_n(2ka)}{K'_n(\kappa_{2j}a)} K_n(\kappa_{2j}r) \right] \\
 & + \left[PV \int_0^{\infty} \frac{C_2}{k} \cosh \kappa(d+z) J_n(\kappa r) d\kappa - C_0 I_{20} \cosh k_2(d+z) \frac{H_n(k_2r)}{k H'_n(k_2a)} \right. \\
 & \quad \left. - \sum_{j=1}^{\infty} C_j I_{2j} \cos \kappa_{2j}(d+z) \frac{K_n(\kappa_{2j}r)}{k K'_n(\kappa_{2j}a)} \right. \\
 & \quad \left. + C_3 C_0 \cosh k_2(d+z) \left[J_n(k_2r) - \frac{J'_n(k_2a)}{H'_n(k_2a)} H_n(k_2r) \right] \right] e^{-i2\sigma t}
 \end{aligned} \tag{15}$$

where the nondimensional coefficients are defined as

$$\begin{aligned}
 C_0 &= \frac{\cosh k_2 d}{\sinh 2k_2 d + 2k_2 d} & C_j &= \frac{\cos \kappa_{2j} d}{\sin 2\kappa_{2j} d + 2\kappa_{2j} d} \\
 C_1 &= \frac{3}{4} \frac{k(\tanh^2 kd - 1)}{\cosh 2kd(2k \tanh 2kd - k_2 \tanh k_2 d)} \\
 C_{10} &= 6 \frac{k^2(\tanh^2 kd - 1)}{4k^2 - k_2^2} & C_{1j} &= 6 \frac{k^2(\tanh^2 kd - 1)}{4k^2 + \kappa_{2j}^2} \\
 C_2 &= \frac{1}{4} \frac{\kappa D_n(\kappa)}{\cosh \kappa d(\kappa \tanh \kappa d - k_2 \tanh k_2 d)} \\
 I_{20} &= \int_0^{\infty} \frac{\kappa^2 D_n(\kappa) J'_n(\kappa a)}{(\kappa^2 - k_2^2)} d\kappa & I_{2j} &= \int_0^{\infty} \frac{\kappa^2 D_n(\kappa) J'_n(\kappa a)}{(\kappa^2 + \kappa_{2j}^2)} d\kappa \\
 C_3 &= \frac{i\pi}{2} \frac{k_2}{k} D_n(k_2)
 \end{aligned}$$

In the solution given by (15), terms enclosed in the first bracket on the right hand side represent: (1) the forced Stokes plane wave component at wavenumber $2k$ and (2) the free cylindrical wave motion due to the scattering of this Stokes plane wave from the cylinder. These terms are found to be identical to a portion of the solution proposed by Chen and Hudspeth (1982), derived using the method of Green's functions. Terms in the second bracket then represent: (1) the remaining forced-radiated wave motion due to other nonlinear wave-wave interactions as well as (2) free scattered waves due to the interaction of these forced-radiated waves with the cylinder. Although derived in an independent way, the solution for these forced wave motions in (10) is identical to that proposed by Garrison (1979), also through application of Green's theorem, as Garrison's Green's function for the free surface potential can be reduced analytically to that given by (10) for a circular cylinder. Garrison then obtains the scattered wave solutions numerically in terms of a second Green's function and an unknown source distribution on the cylinder. The scattered wave motions in the proposed solution are obtained in closed-form based on the complete set of eigenfunction solutions for the homogeneous boundary value problem.

SOLUTION FOR NONLINEAR FREE SURFACE

The first and second-order velocity potentials are substituted into the dynamic free surface boundary condition to evaluate the form of the free surface around the cylinder. Based on the perturbation expansion technique, Φ and η are expanded in power series form, and the dynamic free surface boundary condition is then expanded in a Taylor series about the still water level, $z = 0$. The resulting expression for the water surface, consistent to the second perturbation order, may then be obtained as

$$\eta_1 + \eta_2 = -\frac{1}{g}\Phi_{1t} - \frac{1}{g}\Phi_{2t} - \frac{1}{g^2}\Phi_{1t}\Phi_{1tz} - \frac{1}{2g}\left[\Phi_{1r}^2 + \frac{1}{r^2}\Phi_{1\theta}^2 + \Phi_{1z}^2\right] \quad (16)$$

The resulting wave field, based on the right side of (16), is found to include: (1) linear incident and scattered waves, (2) second-order components from the second-order velocity potential, and (3) second-order components derived from nonlinear product terms of the first-order wave field. These last quadratic terms are found to include both steady components as well as components that oscillate at twice the frequency of the linear waves. All terms may be obtained from a straightforward substitution of the velocity potentials in (3) and (15) into (16); however, the results are quite lengthy and include several double-summations. The interested reader may refer to Kriebel (1987) for details.

In Figures 2 and 3, contours of wave crest amplitudes around the cylinder are shown for the linear and nonlinear diffraction solutions respectively. An example of the predicted wave crest and trough envelopes along the x-axis, as well as around the circumference of the cylinder, is then shown in Figure 4, where second-order mean water levels are also shown. In each figure, results are normalized by the incident wave amplitude and are given for a reference case where $ka = 1.0$, $kd = 1.57$, and where $kH = 0.5$. It is noted, however, that while the nonlinear solution in (15) and in Figure 3 is a function of kH , the nondimensional linear solution in (3) and in Figure 2 is not a function of the wave steepness.

In the up-wave region, the linear scattered wave opposes the linear incident wave to form a partial standing wave system. Second-order components generally increase the crest heights in the antinodes while reducing trough amplitudes. It is found, however, that terms from the second-order velocity potential in (10) are mostly out-of-phase with the linear solution and tend to decrease crest heights while other second-order components are in-phase and lead to the expected increase in crest heights. The nonlinear increase in crest heights is most pronounced on the up-wave cylinder boundary, where runup amplitudes are significantly increased relative to linear theory. Spatially varying mean water levels are also found which are the cylindrical analog to the "corrugated" mean water levels associated with standing waves in front of a vertical plane barrier. These components are superimposed upon the usual uniform set-down associated with the two-dimensional Stokes wave theory.

In the down-wave region, linear incident and scattered waves propagate in generally the same direction and do not generate strong quadratic interactions compared to the up-wave region. At second-order, however, scattered free waves and diffracted waves from the up-wave region propagate away from the cylinder in the down-wave region. These waves are superimposed on the linear waves and their bound second harmonics to produce spatially varying crest and trough envelopes, analogous to those produced by the superposition of first- and second-order free and forced waves in a wave flume. These interactions vary in both r and θ such that significant diffraction patterns are obtained with localized areas of constructive and destructive wave interactions. One result of these interactions is that there is also significant recovery of the wave crest amplitude immediately behind the cylinder at second-order, something that is not predicted by the first-order diffraction theory.

EXPERIMENTAL VERIFICATION

The second-order diffraction theory is verified through comparison to laboratory data for: (1) wave runup and rundown envelopes around the circumference of the cylinder and (2) wave crest and trough envelopes along the x-axis out to a distance of 5 times the cylinder radius. The experiments were conducted in the directional wave basin at the University of Florida Coastal and Oceanographic Engineering Laboratory. The water depth was maintained at 45.0 centimeters with a cylinder radius of 16.25 centimeters, such that a constant depth-to-radius ratio of 2.77 was used for all experiments.

The experiments were conducted with monochromatic long-crested waves and a total of 22 experiments were carried out covering a broad range of the nondimensional parameters. Relative cylinder sizes remained in the diffraction regime with ka values from 0.271 to 0.917. Relative water depths remained in the intermediate depth regime kd values from 0.75 to 2.536. Values of the wave steepness were selected such that Stokes theory would remain convergent, although some waves with very high steepness were also tested; kH values ranged from 0.085 to 0.806. Stokes second-order theory is formally expected to be appropriate for only 8 of the 22 experiments, while higher order wave theories would be most appropriate for the remaining conditions.

Wave runup data were obtained by video-taping the water surface on the circumference of the cylinder as waves passed a grid painted on the outside of the cylinder. Data analysis included selecting a 20 to 30 second period of steady state conditions and then averaging the wave crest runup and trough rundown for 10 waves every 15 degrees around the cylinder. For 12 of the experiments a video record was also made of waves passing a "photopole" array, which consisted simply of 10 thin vertical rods placed in a linear array along the x axis as depicted in Figure 5. The photopole data consists of the wave crest and trough envelopes at each pole location, averaged over 10 waves. The photopole experiments were conducted separately from the runup experiments so that the presence of the poles would not disrupt the other measurements.

Figure 5. Experimental set up showing photopole array along x -axis.

Examples of the first- and second-order theories compared to laboratory wave runup and rundown data are shown in Figures 6 through 8. Based on a comparison of the data to linear theory, several general conclusions may be reached. Maximum wave runup at the front of the cylinder is greater than that predicted by linear theory in all cases and the runup distribution is poorly predicted by the linear theory. At the rear of the cylinder, the wave crest amplitude is also greater than that predicted by linear theory in all cases. Finally, the rundown amplitudes in the front and rear of the cylinder are not as large as predicted by linear theory.

In contrast, the nonlinear diffraction theory provides much better agreement for runup distributions and maxima. From Figure 6, for the smallest relative cylinder size and depth tested, the measured runup profile is almost exactly predicted over all angular positions by the second-order theory, even though this wave steepness is just at the limit of validity of Stokes theory where cnoidal theory may be more appropriate. The rundown envelope is well-predicted only over the rear half of the cylinder in this case.

For larger values of ka and kd , second-order predictions for wave runup distributions are in good agreement with the data for conditions where Stokes second-order theory is expected to be valid. At higher values of kH , however, like that shown in Figure 7, the nonlinear theory predicts substantially larger runup than linear theory but still tends to underpredict the maximum runup. The rundown envelope is predicted fairly well at front and rear, however, the large trough amplitudes predicted near 75° are not displayed in the data, exact for waves of low steepness.

In Figure 8, the runup and rundown envelopes are predicted very accurately, this time even for a condition where Stokes 3rd or higher order theories are most appropriate and where the wave steepness is at nearly 70 percent of the theoretical breaking steepness. In this case, both the maximum runup at the front and at the rear are predicted almost exactly. The rundown distribution is also well-predicted over the leading half of the cylinder, but again is not well-predicted along the sides of the cylinder.

Figure 6. Example of wave runup distribution for $ka = 0.271$, $kd = 0.750$, and $kH = 0.215$.

In Table 1, the measured maximum crest runup is compared to both linear and nonlinear diffraction theories for all experiments. The results indicate that the maximum runup exceeds that predicted by linear theory by 13 to 83 percent and by 44 percent on average for the experimental data set. In contrast, the second-order theory overpredicts the maximum runup by 1 to 5 percent for the first set of conditions, predicts the measured runup to within 0 to 22 percent for most cases, and underpredicts by more than 40 percent for only two tests where the steepness was near breaking. In general, the data exceeds the nonlinear theory by 11 percent on average and by only 8 percent if the two conditions near breaking are excluded.

Figure 7. Example of wave runup distribution for $ka = 0.374$, $kd = 1.036$, and $kH = 0.286$.

Figure 8. Example of wave runup distribution for $ka = 0.917$, $kd = 2.536$, and $kH = 0.631$.

Table 1. Experimental results for maximum wave runup

ka	kd	kH	% Diff.	
			Linear	Nonlinear
0.271	0.750	0.132	27	-2
		0.178	36	-5
		0.215	48	-1
0.308	0.853	0.085	16	1
		0.137	33	5
		0.182	45	6

		0.631	25	0
		0.806	83	43

Examples of the photopole experiments are presented in Figures 9 and 10. The visual observations of the wave crest and trough envelopes are compared to the first and second-order theoretical solutions, which have been extended out to $r = 10a$ to give a better indication of the overall scattering and diffraction patterns along the x axis. In general, the photopole data seem to verify the general features of the wave envelopes predicted by the second-order theory. For the smaller cylinder size, in Figure 9, the second-order scattered waves lead to additional nodes and antinodes in the up-wave region compared to linear theory. The photopole data confirm the positions and magnitudes of these maxima and minima for both the wave crest and trough on the up-wave side. On the down-wave side, the second-order wave components do not produce significant modulations in the envelopes; and, to within measurement accuracy, the data verify this theoretical prediction as well.

The data in Figure 10, for the largest cylinder size tested, show that both the predicted and measured envelopes are similar to the linear envelope except that the crest elevations are increased while troughs are reduced. No secondary maxima are predicted in the envelopes, in contrast to the results at smaller values of ka . On the down-wave side, significant spatial modulation is predicted for this case. Data from the crest envelopes provide a rough verification of these nonlinear diffraction effects, as the presence and approximate spacing of the predicted envelope maxima and minima are confirmed, although the measured envelopes are more poorly defined.

Figure 9. Example of wave envelopes along x-axis for $ka = 0.374$, $kd = 1.036$, and $kH = 0.286$.

Figure 10. Example of wave envelopes along x-axis for $ka = 0.917$, $kd = 2.536$, and $kH = 0.631$.

CONCLUSIONS

The proposed second-order diffraction theory seems to rigorously account for nonlinear wave components including second-order forced waves due to nonlinearities in the free surface boundary condition as well as second-order free waves due to the nonlinear scattering process. Based on comparisons to laboratory data, the theory is then found to realistically predict the nonlinear characteristics of the wave field surrounding the cylinder. A comparison of the theory to previously proposed nonlinear diffraction theories shows substantial agreement in portions of the solution, but not in the entire solution, with the theories of Chen and Hudspeth (1982) and Garrison (1979). Finally, the proposed second-order theory seems to be valid for the same relative depth and wave steepness conditions for which the usual Stokes plane wave theory is valid.

CHAPTER 2

WAVE-CURRENT INTERACTION IN HARBOURS

Jan K. Kostense, Maarten W. Dingemans and Peter Van den Bosch *

ABSTRACT

A finite element model has been developed to study the effect of currents on the wave propagation in and around arbitrarily shaped harbours of variable depth. The model solves an elliptic mild-slope type of equation for time-harmonic waves, and thus circumvents the limitations of existing models for wave-current interaction in coastal areas, which apply a parabolic approximation. Numerical examples are presented, both for schematized cases, as the effect of "rip currents" on normal incident waves on a sloping beach, and for a realistic geometry.

1. INTRODUCTION

An effective tool to study the wave penetration into harbours of variable depth and arbitrary shape is the mild-slope equation as originally derived by Berkhoff (1972). The equation describes the combined effect of bottom refraction and diffraction on the propagation of linear gravity waves. Booij (1981) suggested how to extend the equation to account for dissipative effects. To solve the full elliptic equation, Kostense et al. (1986) presented a finite-element model, which has been implemented with several types of boundary conditions, such as partial reflection, and combined reflection and transmission. They experimentally verified their model for a complex harbour geometry, and showed that it can be successfully applied, for instance to study the dissipative effects of bottom friction and permeable breakwaters on harbour resonances. The implementation of wave breaking in the model is described by De Girolamo, Kostense and Dingemans (1988), while the numerical solution methods are discussed by Hurdle, Kostense and Van den Bosch (1989). The

* Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, the Netherlands

model has been implemented on two different supercomputers, viz. a Cray XMP and a NEC SX/2. Taking advantage of its vector-processors, the system of equations is solved quite efficiently, enabling computations of relatively large areas.

Radder (1979) introduced a parabolic approximation of the mild-slope equation and thus converted a boundary value problem into an initial value problem. The nature of the parabolic approximation is such that diffraction and reflection are neglected in the computational main-wave propagation direction. Since then, this technique was widely applied to study the wave propagation in coastal areas, especially after Booij (1981) introduced an extended equation accounting for the effect of varying currents. Kirby (1984) showed that Booij used an improper form of the dynamic free surface boundary condition, and derived an improved equation.

Apart from coastal regions, currents may also have a noticeable effect on the wave penetration into harbours, especially if they are situated in tidal inlets, in estuaries, near in- and outlets of power plants, etc. Until now this effect could not be incorporated in numerical studies, as parabolic methods inhibit reflections opposite to the main direction of wave propagation. Therefore, the finite element model presented by Kostense et al. (1986) has been modified to solve the equation as derived by Kirby (1984). The model has been given in section 2 and the necessary iteration procedure for the wave direction has been described in section 3. To illustrate the effectiveness of the model, in section 4 a series of computations is discussed, both for schematized cases, and for a realistic geometry.

2. THE EXTENDED MILD-SLOPE EQUATION

For irrotational wave motion, the velocity potential $\Phi(\vec{x}, z, t)$ is written as

$$\Phi(\vec{x}, z, t) = f(z, h) \phi(\vec{x}, t) \quad \text{with} \quad (1)$$

$$f(z, h) = \frac{\cosh[k(h+z)]}{\cosh kh} \quad (2)$$

With an ambient current field $\vec{U}(\vec{x})$ the time-dependent mild-slope

equation results as (Kirby, 1984)

$$\frac{D^2\phi}{Dt^2} + (\nabla \cdot \vec{U}) \frac{D\phi}{Dt} + \phi \frac{D}{Dt} (\nabla \cdot \vec{U}) - \nabla \cdot (cc_g \nabla \phi) + (\omega_r^2 - k^2 cc_g) \phi = 0, \quad (3)$$

where c , c_g and k represent the phase velocity ω_r/k , the group velocity $d\omega_r/dk$, and the wave number $|\vec{k}|$, respectively, ∇ is the two-dimensional gradient operator, and further

$$\frac{D}{Dt} \equiv \frac{\partial}{\partial t} + \vec{U} \cdot \nabla, \quad (4)$$

$$\omega_r = \omega - \vec{k} \cdot \vec{U}, \quad \text{and} \quad \omega_r^2 = gk \tanh kh. \quad (5a, b)$$

Introducing time-harmonic motion,

$$\phi(\vec{x}, t) = \text{Re} \left\{ \psi(\vec{x}) e^{-i\omega t} \right\}, \quad (6)$$

there results

$$\frac{\partial}{\partial x_i} \left[cc_g \frac{\partial \psi}{\partial x_i} - U_i U_j \frac{\partial \psi}{\partial x_j} \right] + 2i\omega U_j \frac{\partial \psi}{\partial x_j} + \left(k^2 cc_g + \omega^2 - \omega_r^2 + i\omega \nabla \cdot \vec{U} \right) \psi = 0. \quad (7)$$

The equation solved in the finite element model is obtained from Eq. (7) by assuming currents which are small compared to the group velocity, and thus neglecting the quadratic term in U . Furthermore, at the right-hand side of the equation the dissipation term is added (see also Hurdle et al., 1989):

$$\frac{\partial}{\partial x_j} \left[cc_g \frac{\partial \psi}{\partial x_j} \right] + 2i\omega U_j \frac{\partial \psi}{\partial x_j} + \left(k^2 cc_g + \omega^2 - \omega_r^2 + i\omega \nabla \cdot \vec{U} \right) \psi = -i\omega_r W \psi. \quad (8)$$

The equation is solved by means of standard finite element techniques, using triangular elements with linear interpolation functions.

3. ITERATION PROCEDURE FOR CURRENT EFFECT

As the relative wave frequency, ω_r , is dependent on the unknown direction of \vec{k} , Eq. (8) can be solved only in an iterative manner. To elucidate the iteration procedure and its underlying assumptions, the case of a traveling wave is considered:

$$\psi(\vec{x}) = b(\vec{x}) e^{iS(\vec{x})} . \quad (9)$$

Inserting this expression into Eq. (8) results into an energy transport equation and the eikonal equation:

$$(\nabla S)^2 = k^2 + \frac{\nabla c c_g}{c c_g} \cdot \frac{\nabla b}{b} + \frac{\nabla^2 b}{b} + \frac{1}{c c_g} \left[(\omega - \vec{U} \cdot \nabla S)^2 - \omega_r^2 \right] . \quad (10)$$

Since the phase function of ϕ reads $\chi(\vec{x}, t) = S(\vec{x}) - \omega t$, the wave number vector as resulting from the (extended) mild-slope equation can be obtained as

$$\vec{\kappa} = \nabla \chi = \nabla S . \quad (11)$$

It is stressed that the absolute value, k , of the initial wave number results as a constant due to the separation of variables in Eq. (1), which splits off the vertical structure from the wave propagation space. Equation (10) shows that in the wave propagation space the absolute value of the wave number vector κ is different from k due to the effects of bottom slope (through $\nabla c c_g / c c_g$), of diffraction (through $(\nabla^2 b)/b$), and of currents. The unknown direction of $\vec{\kappa}$ in the Doppler-shift equation (5a) is now approximated by the resulting direction of $\vec{\kappa}$, resulting from the former iteration step.

The iteration procedure runs as follows. For the first step the relative wave frequency ω_r in Eq. (5a) is obtained assuming either $\vec{U} = 0$, or a direction of $\vec{\kappa}$ equal to the incident wave direction. Then Eq. (8) yields the solution ψ_0 and the wave number vector

$$\vec{\kappa}_0 = \nabla S = \text{Im} \left(\frac{\nabla \psi_0}{\psi_0} \right) . \quad (12)$$

For the second step the direction of $\vec{\kappa}_0$ is used as an estimate for the direction of $\vec{\kappa}$ in Eq. (5a)

$$\omega_r = \omega - \left(\frac{\vec{\kappa}_0}{\kappa_0} k \right) \cdot \vec{U} , \quad (13)$$

from which, together with the dispersion relation (5b), ω_r and k can be solved and substituted into the mild-slope equation. Now the solution

ψ_1 , which yields from the second step, is used to determine $\vec{\kappa}_1$ and ω_r from expressions similar to Eqs. 12 and 13. From hereon the iteration process continues till a certain accuracy is achieved. To determine whether the stopping criterion is met, the procedure is essentially the same as applied for problems involving dissipation, where the magnitude of W is dependent on the local wave potential, see also Kostense et al. (1986) and De Girolamo et al. (1988). The number of occurrences for which the successive iterations of ψ_n differ more than some relative amount from ψ_{n-1} are counted. This is carried out separately for the real and the imaginary part for each of the mesh points:

$$\text{if } \left| \frac{\text{Re}(\psi_n) - \text{Re}(\psi_{n-1})}{\text{Re}(\psi_n)} \right| > \epsilon \text{ then } N_{\circ} = N_{\circ} + 1$$

and also

$$\text{if } \left| \frac{\text{Im}(\psi_n) - \text{Im}(\psi_{n-1})}{\text{Im}(\psi_n)} \right| > \epsilon \text{ then } N_{\circ} = N_{\circ} + 1$$

Here ϵ is a predetermined accuracy of a few percents. With N_{\circ} occurrences at a total of N mesh points, the iteration is stopped when $N_{\circ}/N < 0.01$. Because the real and the imaginary parts are counted separately, deviations may occur in less than 0.5 % of the mesh points. To obtain reliable estimates of $\nabla\psi$ in Eq. 12, a minimum number of about 12 mesh elements per wave length is required. This condition is essentially the same as for bottom friction computations, which also involve the assessment of $\nabla\psi$, see Kostense et al (1986). Fulfilling this condition, usually about 5 iterations appear to be adequate to obtain reliable results of wave-current computations.

4.0 NUMERICAL EXAMPLES

As numerical examples have been selected wave propagation over a rip current, over a vortex ring and, as an example of a realistic geometry, wave penetration in the Malamocco inlet to the Venice Lagoon.

Rip current

To demonstrate the application of the model to wave-current interactions, computations were performed on the effect of a rip current

on the propagation of normally incident waves on a plane beach with a slope of 1/50, a problem that was originally studied by Arthur (1950). The velocity field is given by

$$U_x = -3.60 \left[2 - \left(\frac{y}{76.2} \right)^2 \right] F \left(\frac{y}{76.2} \right) \int_0^{\frac{x}{7.62}} F(\sigma) d\sigma$$

$$U_y = 0.4731 y F \left(\frac{y}{76.2} \right) F \left(\frac{x}{7.62} \right)$$

with

$$F(\sigma) = (1/\sqrt{2\pi}) \exp(-\sigma^2/2)$$

and is illustrated in Fig. 1. This Figure also shows Arthur's results for a wave period of 8 seconds. These results were obtained with the ray approximation method, which allows for refraction and shoaling only and thus yields unlimited wave heights where the rays cross each other.

Fig. 2 shows two wave height distributions - without and with the effect of wave breaking - obtained from the finite element model. For these computations a grid of 74,003 nodes was used. For nonbreaking and breaking conditions, the computations required 5 and 8 iterations, respectively. The conditions are the same as applied by Arthur. To quantify the effect of wave breaking the formulation given by Battjes and Janssen (1978) has been used, see De Girolamo et al. (1988). Comparing both wave height distributions, the inclusion of wave breaking appears to yield more stable results.

It should be noted that the results in Fig.2 could have been approximated satisfactory by parabolic models, see e.g. Kirby (1983). The reason to perform these computations was to show that nowadays supercomputers enables one to cope with relatively large areas, to which one would have been compelled by the presence of any reflective constructions, such as groynes.

Vortex ring

The model has also been applied to study the wave propagation over a vortex ring in constant water depth. Examples of the occurrence of

Figure 1 Typical rip current, from Arthur (1950)

without breaking

with breaking

$H_s = 0.20 \text{ m}$

$T = 8.0 \text{ s}$

Wave height in m

Figure 2 Rip current; wave height distributions without and with breaking

vortex rings in nature are the Gulf stream warm-core rings and the large-scale vortices along the Norwegian coast. The finite element grid, which was used for this study consisted of 114,661 nodes, representing a circular area with a diameter of 5 km. The shape of the current velocity distribution is essentially the same as applied by Yoon (1987): the radial velocity component $V_r = 0$ and the tangential velocity given by

$$V_{\theta} = C_1 \left(\frac{r}{R_1} \right)^N \quad \text{for } r \leq R_1, \text{ and}$$

$$V_{\theta} = C_2 \exp \left[- \left(\frac{R_2 - r}{R_3} \right)^2 \right] \quad \text{for } r > R_1.$$

The maximum velocity C_2 occurs along the circle $r = R_2$. For the numerical computation the coefficients were taken to be $C_1 = 0.9$ m/s, $C_2 = 1.0$ m/s, $R_1 = 900$ m, $R_2 = 1000$ m, $R_3 = 300$ m and $N = 2$. Fig. 3 shows the current velocity distribution, which rotates clockwise. For a water depth of 100 m, a wave period of 10 seconds and an incident wave height of 1.0 m the wave height distribution resulting from a computation without dissipation is shown in Fig. 4. The computation required 7 iterations. In the lower part of the graph the wave directions diverge due to current refraction, resulting in low waves. This area is bounded by a caustic line, where the refracted waves interact with the undisturbed ones. Diffraction in lateral direction precludes unlimited wave heights along this line. The consecutive caustic lines in the upper part of the graph originate from converging wave directions.

Malamocco inlet to the Venice Lagoon

An example from engineering practice of the effect of an ambient current is the wave penetration of the Malamocco inlet to the Venice Lagoon, which was computed as part of the project to develop a flood defence system for Venice. The schematization of the inlet and the bottom topography, as well as a representative ebb current field, are illustrated in Fig. 5. The computational grid comprised 249,088 nodes. The wave field was computed for a water level of CD + 0.80 m, representing mean sea level, and for waves incident from a bearing of 137° N with a height of 1.8 m and a period of 8 seconds.

$$V_r = 0$$

$$V_\theta = C_5 \left[\frac{r}{R_1} \right]^N \quad \text{for } r < R_1$$

$$V_\theta = C_6 \exp \left[-\left(\frac{R_2 - r}{R_3} \right)^2 \right] \quad \text{for } r \geq R_1$$

with:

$$C_5 = 0.9 \text{ m/s}$$

$$C_6 = 1.0 \text{ m/s}$$

$$R_1 = 900 \text{ m}$$

$$R_2 = 1000 \text{ m}$$

$$R_3 = 300 \text{ m}$$

$$N = 2$$

Figure 3 Vortex ring; current velocity profile

Figure 4 Vortex ring; wave height distribution

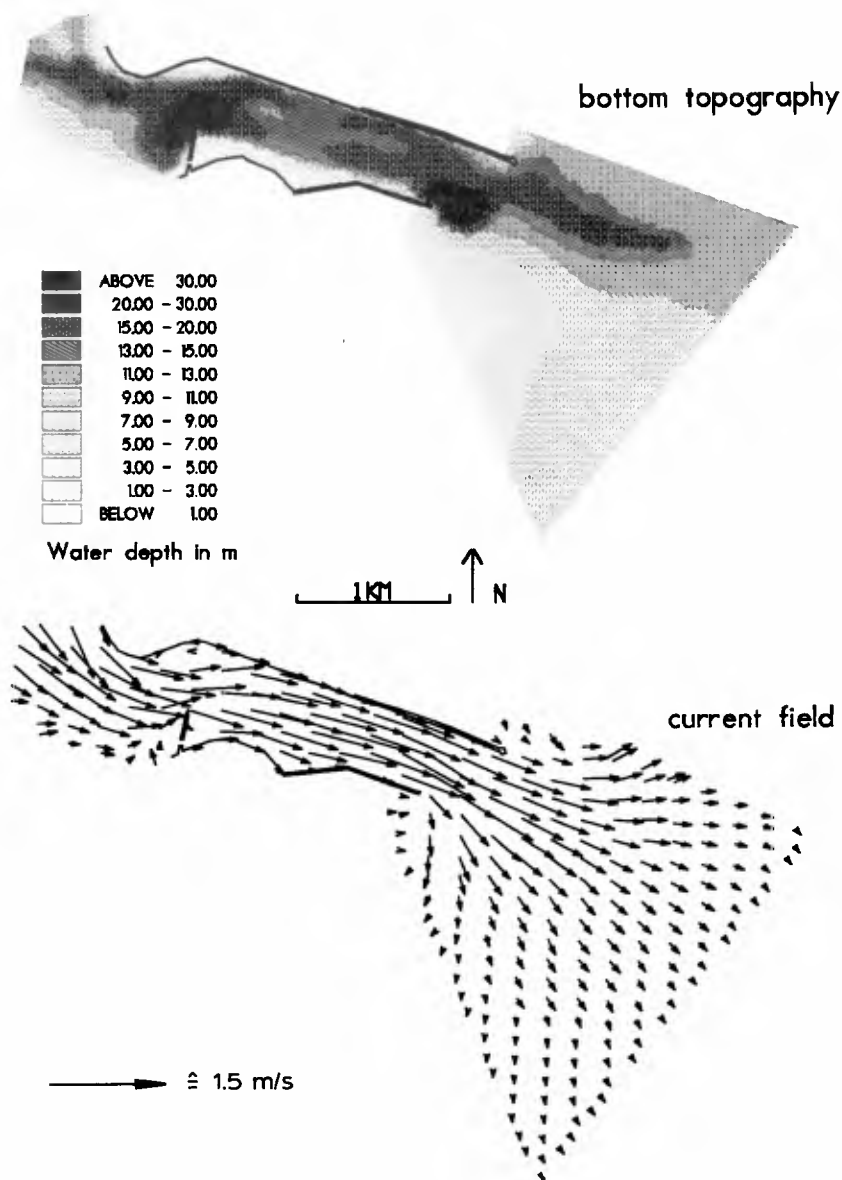

Figure 5 Malamocco inlet to the Venice lagoon area; bathymetry and typical ebb currents

The results, with and without current, are shown in Figure 6. The wave height distribution for the no current case shows a focussing of energy along the south side of the entrance channel due to so-called channel refraction. This also results in a reduction of the wave height in the channel region. The inclusion of the ebb current in the computation results in a significant increase in penetration of the inlet. This is due to the effects of current refraction, which offset the effects of bottom refraction on the south slope of the channel. The computation with current required 4 iterations and was executed on a NEC SX/2. The required CPU time was 42 minutes at a performance of 250 Mflop/s.

5. DISCUSSION

The effect of ambient currents on wave propagation in and around harbours and coastal regions with reflective boundaries can be determined by means of a finite element model solving an extended mild-slope equation. Contrary to the original mild-slope equation for bottom refraction and diffraction only, the extended equation should be solved in an iterative way, as beforehand the wave direction in the computational region is unknown. Apart from the strength of the currents, the number of iterations depends on the number of elements per wave length. For stability reasons a minimum number of about 12 elements per characteristic wave length is required to obtain accurate estimates of the gradient of the velocity potential. This number is essentially the same as applied for the dissipative effects of bottom dissipation, see Kostense et al. (1986). For non-iterative computations without currents and dissipation the number of elements is determined by the desired accuracy; for engineering purposes usually about 8 elements per characteristic wave length are applied.

The presented numerical examples show that the extended model successfully integrates the effects of diffraction, bottom refraction, current refraction, reflection and dissipation. Moreover, it is shown that even relatively weak currents may have a significant influence on the wave propagation.

6. ACKNOWLEDGEMENT

The case study results shown in Fig.6 were established within the scope

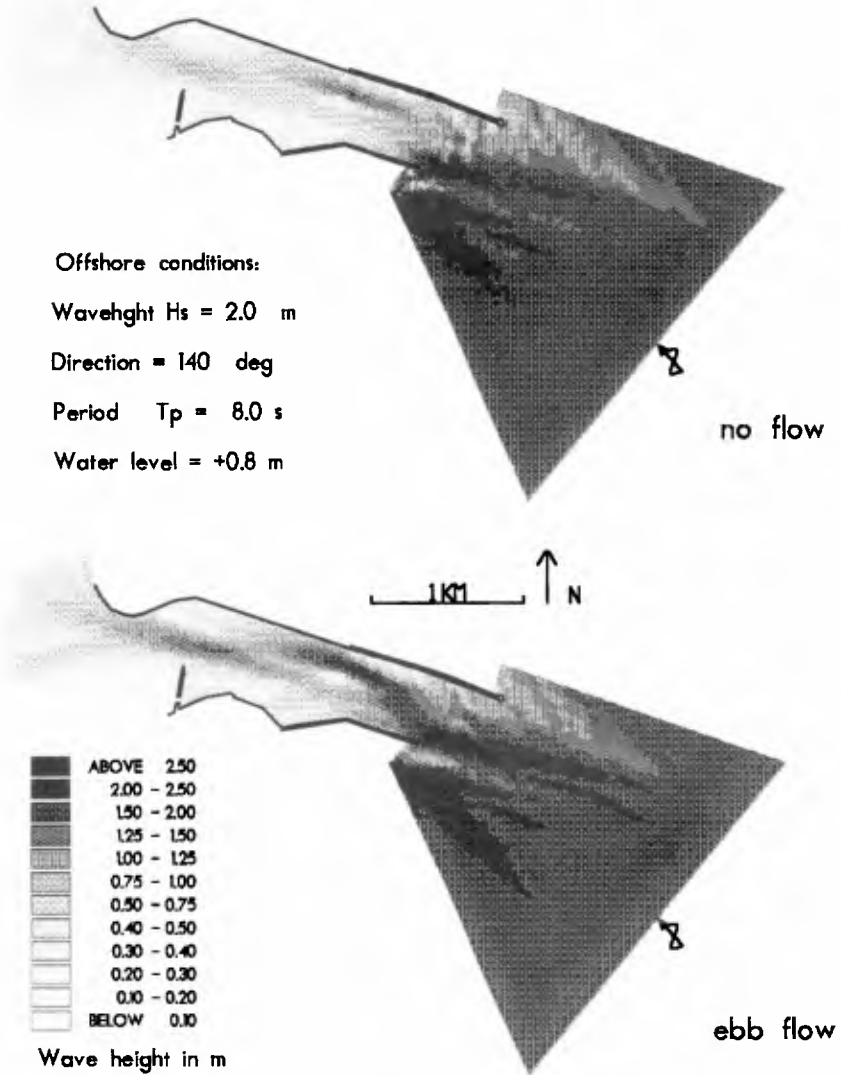

Figure 6 Malamocco inlet to the Venice lagoon area; effect of an ambient current field on the wave height distribution

of a study of the wave behaviour at the Venice Lagoon inlets, which study was commissioned to Delft Hydraulics by Consorzio VENEZIA NUOVA.

CHAPTER 3

OBSERVATION OF DIRECTIONAL WAVE SPECTRA AND REFLECTION COEFFICIENT OF BREAKWATER IN A HARBOR

by

Tetsunori Ohshimo*, Kosuke Kondo**, and Tsunehiro Sekimoto*

ABSTRACT

Field investigations were performed in order to show the effect of wave diffraction by breakwaters through directional wave spectra measurements in a harbor, and to estimate the reflection coefficient by resolving the incident and reflected wave energy in front of a composite type breakwater. Combinations of an ultrasonic wave gage (USW) and an electromagnetic current meter (EMC) were used to measure the synchronized data of the water surface elevation and two horizontal velocities. The EMLM (Extended Maximum Likelihood Method) was applied for the calculation of the directional wave spectrum, and the modified EMLM for an incident and reflection wave field was applied for the estimation of the reflection coefficient. Through the estimated directional wave spectra, the effect of wave diffraction by breakwaters were discussed and the reflection coefficient was estimated at about 0.9. As a result, the applicability of the field investigation method and the modified EMLM were verified.

1. INTRODUCTION

In the design of maritime structures it is necessary to estimate not only the characteristic height and period parameters but also the random nature of sea waves. To describe the irregularity of sea waves with different frequencies and directions, the concept of directional wave spectrum is of great importance, since the directional wave spectrum employs both the frequency and the wave direction. It is basically possible to determine the directional wave spectrum of random sea waves by use of various methods and instruments. As there have been recent remarkable advances in the theories for estimating the directional wave spectrum, many field investigations have also been performed.

Among the methods for computation of directional spectrum, the Maximum Likelihood Method (MLM) is known to yield the highest directional resolution. However, it is applicable only to wave gage array measurements. So, Isobe, Kondo,

* Engineer, Design and Engineering Department, Penta-Ocean Construction Co., Ltd., 2-2-8 Koraku, Bunkyo-ku, Tokyo, 112 Japan.

** Principal Engineer, Design and Engineering Department, Penta-Ocean Construction Co., Ltd., 2-2-8 Koraku, Bunkyo-ku, Tokyo, 112 Japan.

and Horikawa (1984) extended the MLM to mixed arrays and named it the Extended Maximum Likelihood Method (EMLM). For the estimation of the directional spectrum by the EMLM, a set of data records of various wave properties at one point is sufficient. Moreover, at sites where wave transformation such as that due to refraction and diffraction is significant, the EMLM makes it possible to obtain the local directional wave spectrum. But the EMLM is not applied for the estimation of the directional wave spectrum near the reflection line, because the phase lag between the incident and reflected waves is not random. It is necessary to consider the fixed phase relation of each pair of incident and reflected wave components. So, the EMLM is modified for calculating the directional spectrum in the wave reflection system similar to the relation between the MLM and the MMLM (Isobe and Kondo, 1984). This method is termed the EMLM-2. It is possible to estimate the reflection coefficient of a vertical wall type breakwater by using the EMLM-2. This method to find the reflection coefficient of prototype structures is much easier than the other methods, because of one-point measurement.

The object of this study is to elucidate the diffracting characteristics through the change of the directional wave spectra calculated by the EMLM, and to estimate the reflection coefficient by analyzing the directional wave spectra by the EMLM-2.

2. FIELD INVESTIGATION

2.1 Site Location and Period of Investigation

The field investigations were carried out in the eastern shore of the Japan Sea at Kashiwazaki, Niigata prefecture, Japan, from January through February, 1986. A location map of the investigation site is shown in figure 1. As geographical features, Sado island and Noto peninsula lie north and west of the study area, respectively. So the dominant wave directions during storm are almost limited from northwest to west.

2.2 Harbor Layout and Field Investigation Program

Figure 2 explains the harbor layout and positions of the instrument combination of a wave gage and a current meter. The Harbor layout is a complex shape in order to keep the harbor tranquil, prevent retention of coastal sediment, allow free flow of water, and so on. Therefore, the wave transformation due to diffraction in the harbor is fairly intricate.

The field investigation program consisted of :

- 1) measurements of incident waves at location free from the effects of breakwaters (point P0);
- 2) measurements of waves diffracted by breakwaters (point P1, P3, and P4); and
- 3) measurements of diffracted and reflected waves in front of the south breakwater (point P2).

Figure 1 Location map of the investigation site

Figure 2 Harbor layout and positions of measuring point

In the third set of measurements, the distance between point P2 and the south breakwater was calculated beforehand, because the accuracy in estimating the directional wave spectra and the reflection coefficient changes depended upon the ratio of distance between the instruments and the breakwater (X) to wave length (L).

Schematic profile of the south breakwater, which is a composite type breakwater without wave energy dissipation, is given in figure 3. This figure also shows the location of point P2 where the instruments were installed at the distance of 32.0 m away from the south breakwater.

Figure 3 Schematic profile of the south breakwater

2.3 Measuring Instruments and Data Sampling Mode

Combinations of the ultrasonic wave gage (USW) and the electromagnetic current meter (EMC) were located on the bottom of the sea. The distance between USW and EMC is about 1.0 m and timing is synchronized through an electrical cable link. Therefore this measuring system is considered "one-point measuring" in terms of field scale.

USW acts as a reversed echo sounder to measure the surface elevation and EMC measures the two components of the horizontal water particle velocity at orthogonal angles. Data is measured for approximately 9 minutes every 2 hours, containing 1022 samples with an interval of 0.5 second, and stored on cassette tape inside the instrument.

3. METHOD OF DATA PROCESSING

3.1 Statistical Analysis

Both the USW and EMC data sometimes contained more noise spikes than were acceptable for statistical analysis. The data records were therefore semi-automatically corrected on a graphics terminal, which allowed an immediate visual check of corrections. All data were analyzed statistically, including the calculation of significant wave height and period by the zero-up-crossing method, principal wave direction and current velocity, etc.

3.2 Directional Spectrum Analysis

In the analysis of the directional spectrum with no reflected waves, that is, at positions P0, P1, and P3, the EMLM was applied for the calculation of the directional wave spectrum. In the analysis of the directional wave spectrum in the wave reflection system, however, the fixed phase relation of each pair of incident and reflected wave components should be considered. Therefore, the EMLM was modified to estimate the directional wave spectrum and the reflection coefficient in an incident and reflected wave field, according to the relation between the MLM and the MMLM (Isobe and Kondo, 1984). A directional wave spectrum and a reflection coefficient can be estimated as follows:

$$\hat{S}(k, \sigma) = \alpha \left[\sum_{m,n} \phi_{mn}^{-1} \cdot \{ H_m^*(k, \sigma) \exp(-ikx_m) + r H_m^*(k_r, \sigma) \exp(-ikx_{mr}) \} \right. \\ \left. \times \{ H_n(k, \sigma) \exp(ikx_n) + r H_n(k_r, \sigma) \exp(ikx_{nr}) \} \right]^{-1} \quad (1)$$

$$r = - \frac{\sum_{m,n} \phi_{mn}^{-1} \{ H_m^*(k, \sigma) \cdot H_n(k_r, \sigma) \cdot \exp\{ik(x_{nr} - x_m)\} + H_m^*(k_r, \sigma) \cdot H_n(k, \sigma) \cdot \exp\{ik(x_n - x_{mr})\} \}}{2 \sum_{m,n} \phi_{mn}^{-1} H_m^*(k_r, \sigma) \cdot H_n(k_r, \sigma) \cdot \exp\{ik(x_{nr} - x_{mr})\}} \quad (2)$$

where k is the wavenumber vector, σ is the angular frequency. $\hat{S}(k, \sigma)$ means the estimated wavenumber-frequency spectrum. r denotes the reflection coefficient. $\phi_{mn}(\sigma)$ is the cross-power spectrum of the water surface and horizontal velocity variations at point x_m and point x_n . H is the transfer function and $*$ denotes the complex conjugate. α is a proportionality constant which can be determined from the relationship between the wavenumber-frequency spectrum and the power spectrum. When the reflection coefficient r equals zero, it completely coincides with that for the EMLM. The present method is termed the EMLM-2.

3.3 Numerical Simulation of EMLM-2

Applying the MMLM for estimating the directional wave spectrum in an incident and reflected wave field, the resolution power of the directional wave spectrum depends on the number and the arrangement of wave gages. In general, the resolution power increases with increasing number of wave gages, and spurious spectral peaks appear if the nearest wave gage is located farther than about $0.2L$ from the reflection line (L : wave-length). Therefore, in the analysis of the directional wave spectrum, using the EMLM-2, it is considered that the resolution power of the directional wave spectrum also depends on the number and arrangement of instruments.

Numerical simulations were performed to example the validity of the EMLM-2. The procedure for the numerical simulation is as follows:

- 1) Specify a functional form for the directional spectrum,

$S(k, \sigma)$, and reflection coefficient, r . Here, the Mitsuyasu-type directional distribution expressed by equation (3) was used. The reflection coefficient was assumed constant for every directional component of waves.

$$S(k, \sigma) = \cos^{2s} \{ (\theta - \theta_0) / 2 \} \quad (3)$$

where θ_0 is a principal wave direction and s is a parameter respecting the degree of directional energy concentration.

- 2) Calculate $\phi_{mn}(\sigma)$ for all given components using the relationship between the cross-power spectrum and the directional wave spectrum in an incident and reflected wave field, which is expressed by equation (4).

$$\begin{aligned} \phi_{mn}(\sigma) = & \int_k S(k, \sigma) \\ & \times \{ \exp(ikx_m) + r \exp(ikx_{mr}) \} \\ & \times \{ \exp(-ikx_n) + r \exp(-ikx_{nr}) \} dk \end{aligned} \quad (4)$$

- 3) Estimate the directional energy distribution from equation (1) and compare to the given one.

Figure 4 shows the definition sketch of an incident and reflected wave field for numerical simulation. X is the distance between the measuring point and the reflective wall, and θ is the wave direction. In this simulation the calculation conditions were set as the typical conditions in this field investigation. For example, the wave period was 8 seconds, the degree of energy concentration was 100, the wave direction was 60 degrees from perpendicular to the breakwater and the given reflection coefficient was 0.90. The number of measuring component was 3 and the distance between USW and EMC was 0.0 m.

Moreover the distance between the reflection line and measuring point, X , is an important parameter to keep the accuracy of estimating the directional wave spectrum and the reflection coefficient. So the three ratio of the distance, X , and wave length, L , that is, $X/L=0.2, 0.5$, and 1.0 were set for the conditions of numerical simulations.

Figure 5 shows examples of the numerical simulation, and R_s and R_p are the estimated reflection coefficients by use of the methods mentioning in 4.4. When $X/L=0.2$, the resolution power is highest and the estimated reflection coefficient also agrees with the given one. When $X/L=0.5$, the estimated reflection coefficient also agrees with the given one, though the resolution power goes down a little and spurious peaks appear around 270 degrees. When $X/L=1.0$, the resolution power goes down considerably and the

Figure 4 Definition sketch of an incident and reflected wave

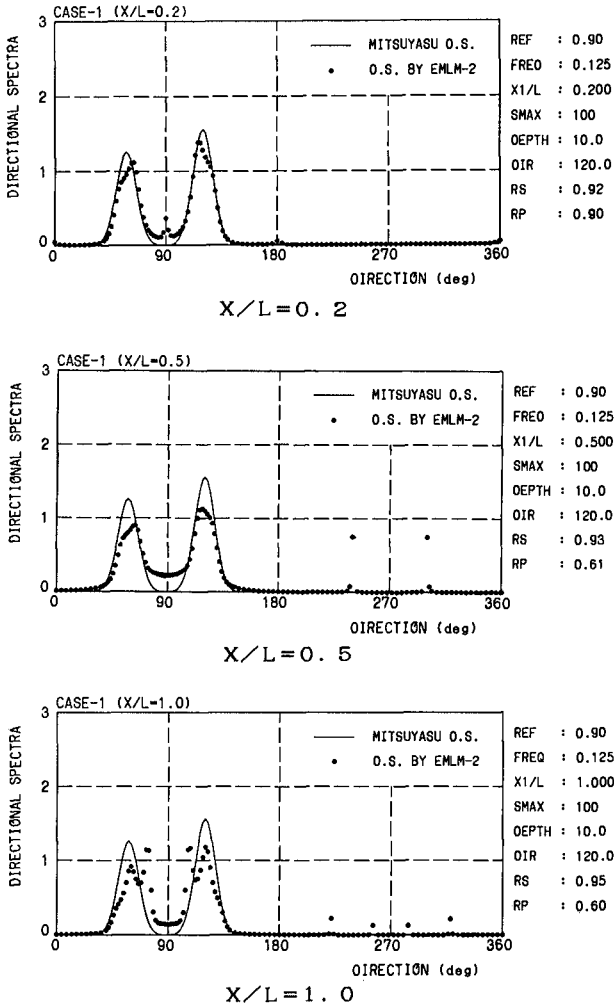

Figure 5 Examples of numerical simulation

estimated reflection coefficient does not agree with the given one.

So, if the measuring point is located far from the reflection line, the resolution power goes down and spurious peaks appear in the estimated spectrum. It is necessary that X/L should be set less than 0.2 in order to keep the accuracy of estimating both the directional wave spectrum and the reflection coefficient, and that X/L should be set less than about 0.5 in order to keep the accuracy of estimating the reflection coefficient.

4. RESULTS

4.1 Wave Conditions

The wave conditions such as significant wave height, significant wave period and principal wave direction during the observation periods are shown in figure 6. As the significant wave heights were always more than 1.0 m, sometimes reaching 2.0 m to 3.0 m, the wave climate was very rough during the period of investigation. The most prevalent significant wave period was about 6 s to 8 s, though it seems that the wave periods become longer in accordance with the increase of wave height. The wave directions clearly changed from west to north in accordance with the increase of wave height. This change of the wave direction followed a move of a low atmospheric pressure.

4.2 Wave Characteristics in a Harbor

Figure 7 shows the relationship between the incident wave direction and the ratio of incident and diffracted wave heights, and compares the diffracted wave direction to the incident wave direction. Symbols are field data and the solid line is the results of numerical simulation in respect of harbor tranquility (Kondo, Shimizu, and Yamada, 1987).

In numerical simulation, the incident directional wave spectrum was considered of a combination of the Bretschneider-Mitsuyasu-type frequency spectrum and the Mitsuyasu-type directional distribution, instead of the observed directional wave spectrum. The other input conditions were typically determined in consideration of mean wave climate during investigations, that is, the significant wave period of 7 s and the degree of energy concentration, S_{max} , of 25, were chosen.

As regards the rate of significant wave heights, field data exhibits the gradual increase according to the change of incident wave direction from west to northwest because of the shelter of the south breakwater.

Comparing between two wave directions at position P0 and P1, the characteristic of the diffracted wave by the south breakwater is obviously recognized. That is to say, when the incident wave directions are west to northwest, the diffracted wave directions are constantly northwest which is

(a) 1st investigation period

(b) 2nd investigation period

Figure 6 Wave conditions during the observation periods

(a) Ratio of the incident and diffracted wave height

(b) Comparison of the incident and diffracted wave direction

Figure 7 Wave characteristics in a harbor

a straight line direction from the tip of the south breakwater to the measuring point. When the incident wave directions are northwest to north, the diffracted wave directions change in accordance with the incident one. The results of numerical simulation show good agreement with field data.

4.3 Change of Directional Wave spectra due to Diffraction

In order to estimate the effect of wave diffraction due to the south breakwater through the directional wave spectra, the directional wave spectra were computed for three different incident wave direction data sets as shown in table 1.

Table 1 Cases for estimating the directional wave spectrum

CASE NO.	DATE	WAVE DIRECTION	H _{1/3} (m)	T _{1/3} (s)
1	1/17 12:00	W (N96° W)	1.31	4.9
2	1/22 12:00	WNW (N64° W)	2.09	5.6
3	1/15 12:00	NNW (N14° W)	1.30	5.0

Examples of the estimated directional wave spectrum are shown in figure 8. Each figure consists of the directional energy distribution contour (central part), the frequency spectra (upper part) and the directional spreading function (righthand part), estimated using the EMLM. The upper three figures are the results at position P0. The lower three figures are the results at position P1.

When the incident wave direction is west, the south breakwater causes a change between the two directional wave spectra as follows.

- 1) The directional peak of incident wave changes to a straight line direction from the tip of the south breakwater in the sheltered area.
- 2) The degree of energy concentration of the directional spreading function in the sheltered area becomes higher than that of the incident wave.
- 3) The frequency power spectrum at sheltered area is different from that at incident area, and the significant wave period changes shorter in the sheltered area. This is because the wave energy included between 0.15 Hz and 0.18 Hz frequency band is more sheltered than that included between 0.21 Hz and 0.24 Hz frequency band.

On the other hand, when the incident wave direction is north-north-west, the two directional wave spectra are almost similar. In this case the south breakwater hardly influences the change of the directional wave spectrum in the sheltered area.

When the incident wave direction is west-north-west that is intermediate direction between the above-mentioned two cases, the change of two directional wave spectra also shows the intermediary characteristics.

Figure 8 Examples of the estimated directional wave spectrum by the EMLM at positions P0 and P1

Figure 9 shows the three directional wave spectra at positions, P0, P1, and P3, in order to understand the effect of wave diffraction by breakwaters more than ever. In the incident directional wave spectrum, the swell and wind wave co-exist, but two wave directions are different, that is, the swell direction with 0.12 Hz to 0.15 Hz frequency is north-west, and the wind wave direction with 0.18 Hz to 0.24 Hz frequency is west. The frequency power of the swell is lower than that of the wind wave at position P0. But at position P1, the frequency power of the swell becomes higher than that of the wind wave. This tendency is more clear at position P3 which is sheltered by both the south breakwater and the north jetty, therefore, the swell only enters into the interior of the harbor.

Figure 9
Examples of the estimated wave spectrum

4.4 Reflection Coefficient and Directional Wave Spectra

(1) Reflection Coefficient

In estimating the reflection coefficient, there are the following two methods. Equation (2) gives an estimation of the reflection coefficient (R_s) for each frequency and for each direction. The second method (R_p) is to adopt the square root of the ratio between the integrated reflected and incident wave energy.

The estimated reflection coefficient by the second method are shown in table 2. In accordance with the results of the numerical simulation, the integrated reflected and incident wave energy between 0.03 Hz and 0.15 Hz was only used for estimating the reflection coefficient, in order to keep the accuracy of estimation. Thus, ten cases including higher wave energy in the frequency range of 0.03 Hz to 0.15 Hz were chosen.

The reflection coefficient shows rather stable values between 0.75 and 0.99 with a mean value of 0.86. Judging from approximate values (0.7-1.0) of the reflection coefficients for a vertical wall as reported in various sources (Goda, 1985), this value is valid.

- (2) Directional wave spectra in incident and reflected wave field.

Figure 10 shows examples of the estimated directional wave spectrum at position, P2, that is, in front of the south breakwater. The EMLM-2 was applied for estimation. 0 degree means that the wave direction is perpendicular to the south breakwater, and 90 degrees is parallel to the south breakwater. The wave direction is defined anti-clockwise. The estimated directional wave spectra have two peaks in symmetrical positions. The direction of the first peak is about 65 degrees, and that of second peak is about 115 degrees.

Judging from the harbor layout, it is understood that the first peak corresponds to the incident wave which come from the tip of the south breakwater, the second peak corresponds to the reflected wave which are set as mirror images of the incident wave at south breakwater. The directional peaks of the incident and reflected waves are sufficiently separated to permit use of the EMLM-2 for estimating the directional wave spectrum.

The peaks between 180 degrees and 360 degrees are, however, regarded as spurious peaks in consideration of the harbor layout and the results of numerical simulation.

Figure 11 shows example of the directional wave spectrum at position, P2, for the same data set with Figure 10, by use of the EMLM. There are also the directional peaks of the incident and reflected wave in this result, whereas the resolution power is lower than the result of the EMLM-2.

5. CONCLUSIONS

The wave measurements were carried out by means of combinations of a wave gage and a current meter. The field data was processed to estimate the directional wave spectra by the EMLM and the EMLM-2, which is the modified EMLM for calculating the directional wave spectrum in an incident and reflected wave system. The effect of diffraction by breakwaters were discussed through the transformation of the directional wave spectra, and the reflection coefficient of the composite type breakwater, without wave energy dissipation, was estimated at a mean value of 0.86. As a result, the applicability of the field investigation method and the EMLM-2 were verified.

CHAPTER 4

DIRECTIONAL SPECTRUM ESTIMATION

FROM A BAYESIAN APPROACH

Noriaki Hashimoto* and Koji Kobune**

ABSTRACT

A new directional spectral estimation method using a Bayesian approach is proposed. The proposed method is examined for numerical simulation data, and the validity of the method is discussed. Some examples of the directional spectra estimated from field observation data attained at an offshore oil rig utilizing seven wave probes are also shown in this report. The major conclusions of the report are : (1) The proposed method can be applied for more than four arbitrarily mixed instrument array measurements. (2) It has a higher resolution power than other existing methods for estimating directional spectrum. (3) It is a better method for estimating directional spectra from the cross-power spectra contaminated with estimation errors. (4) It is more adaptable to reformulation of the estimation equations as the study of structures of directional spectrum progresses.

1. INTRODUCTION

Directional spectra are the fundamental properties of ocean waves expressing the energy distribution as a function of the wave frequency and direction of wave propagation. Many efforts have been made to estimate directional spectra on the bases of point measurements utilizing various wave probes, and several methods have been proposed to improve the directional resolution of the estimation.

These methods are based on a mathematical relationship between the directional spectrum and the cross-power spectra. The cross-power spectra are computed from time series records of various wave properties. In practice, wave records are often contaminated with noises. This leads to errors in the cross-power spectral estimation. Thus, the estimate of the directional spectrum is often biased by the noises and errors associated with the observed cross-power spectra.

However, no current methods take into account the existence of such errors. The directional spectrum is estimated only to satisfy the above mentioned relationship with the observed cross-power spectra, and this may be one of the causes that estimates of the directional spectrum sometimes result in poorly conditioned shape, i.e. negative values or zigzags, for instance.

The same type of problems are seen in the field of the regression analysis problems where the number of the parameters to be estimated is large compared with the sample size. In order to overcome these difficulties, Akaike(1980) introduced a Bayesian model which better approximates the sample data, and which is compatible with an a priori condition subsistent in the phenomenon to be analyzed.

The estimation of the directional spectrum can be considered as a regression analysis problem to find the most suitable model from limited data. Therefore, the Bayesian approach should be useful to obtain the most reasonable model (directional spreading function) which best approximates the sample data (cross-power spectra) and which also conforms to the subsistent nature of the physical phenomenon, i.e., continuous and smooth variation of its value. This is accomplished by maximizing the likelihood of the model with a priori condition that the directional spreading function varies smoothly over the wave direction.

In the practical computation, another parameter which is called a hyperparameter, is introduced to consider the balance of the two requirements imposed on the model : to maximize the likelihood of the model and to maintain the smoothness of the model. In order to select the most suitable value of the hyperparameter for the given cross-power spectra, the ABIC (Akaike's Bayesian Information Criterion, 1980) is also introduced as a criterion to determine the most suitable model.

The proposed method is examined by numerical simulations, and its application to a practical directional wave analysis is also presented with the data recently recorded on an offshore oil rig at a water depth of 150 meters.

2. FUNDAMENTAL EQUATIONS RELATED TO DIRECTIONAL SPECTRUM

The relationship between the cross-power spectrum for a pair of arbitrary wave properties and the directional spectrum is introduced by Isobe et al.(1984) as the following equation :

$$\begin{aligned} \Phi_{mn}(f) = \int_0^{2\pi} H_m(f, \theta) H_n^*(f, \theta) [\cos \{k(x_{mn} \cos \theta + y_{mn} \sin \theta)\} \\ - i \sin \{k(x_{mn} \cos \theta + y_{mn} \sin \theta)\}] S(f, \theta) d\theta \end{aligned} \quad (1)$$

where f is the frequency, k is the wave number, θ is the wave propagation direction, $\Phi_{mn}(f)$ is the cross-power spectrum between the m -th and the n -th wave properties, $H_m(f, \theta)$ is the transfer function from the water surface elevation to the m -th wave property, i is the imaginary unit, $x_{mn} = x_n - x_m$, $y_{mn} = y_n - y_m$, (x_m, y_m) is the location of the wave probe for the m -th wave property, $S(f, \theta)$ is the directional spectrum and the superscript * denotes the complex conjugate.

The directional spectrum $S(f, \theta)$ is often expressed as a product of the frequency spectrum and the directional spreading function.

$$S(f, \theta) = S(f) G(\theta|f) \quad (2)$$

where, $S(f)$ is the frequency spectrum and $G(\theta|f)$ is the directional spreading function. The directional spreading function takes non-negative values and satisfies the following relationship.

Table 1 Transfer function from small amplitude wave theory

MEASURED QUANTITY	SYMBOL	$h(k, \sigma)$	α	β
Water surface elevation	η	1	0	0
Excess pressure	p	$\rho g \frac{\cosh kz}{\cosh kd}$	0	0
Vertical water surface velocity	η_t	$-i\sigma$	0	0
Vertical water surface acceleration	η_{tt}	$-\sigma^2$	0	0
Surface slope (x)	η_x	ik	1	0
Surface slope (y)	η_y	ik	0	1
Water particle velocity (x)	u	$\sigma \frac{\cosh kz}{\sinh kd}$	1	0
Water particle velocity (y)	v	$\sigma \frac{\cosh kz}{\sinh kd}$	0	1
Water particle velocity (z)	w	$-i\sigma \frac{\sinh kz}{\sinh kd}$	0	0

k : wave number, σ : angular frequency, d : water depth, z : elevation from the bottom, ρ : fluid density, g : gravitational acceleration.

$$\int_0^{2\pi} G(\theta|f) d\theta = 1 \quad (3)$$

The transfer function $H_m(f, \theta)$ in Eq.(1) is generally expressed in the form

$$H_m(f, \theta) = h_m(f) \cos^{\alpha_m \theta} \sin^{\beta_m \theta} \quad (4)$$

where the function h_m and the parameter α_m and β_m in Eq.(4) are shown in Table 1.

Equations (1) are the fundamental equations for the estimation of the directional spectrum on the basis of the simultaneous measurements of various wave properties. If the function $S(f, \theta)$ which satisfies Eq.(1) and which takes only non-negative values is obtained, the function is called a directional spectrum.

3. ESTIMATION OF DIRECTIONAL SPECTRUM FROM THE BAYESIAN APPROACH

The directional spreading function takes values greater than or equal to zero, but in this section, the function is treated as a function which always takes positive values only.

Firstly, it is assumed that the directional spreading function is expressed as a piecewise-constant function over the directional range from 0 to 2π ($K\Delta\theta=2\pi$). This assumption is commonly employed in the numerical computation of random waves.

Since $G(\theta|f) > 0$, and let

$$\ln G(\theta_k|f) = x_k(f), \quad (k=1, \dots, K) \tag{5}$$

the directional spreading function is approximated by the following equation.

$$G(\theta|f) = \prod_{k=1}^K \exp\{x_k(f)\} I_k(\theta) \tag{6}$$

where,

$$I_k(\theta) = \begin{cases} 1 & : (k-1)\Delta\theta \leq \theta < k\Delta\theta \\ 0 & : \text{otherwise,} \quad (k=1, \dots, K) \end{cases} \tag{7}$$

Substituting Eq.(6) into Eq.(1) and after some manipulation, the following equation is obtained considering the errors $\epsilon_{mn}(f)$ of the cross-power spectra.

$$\phi_i(f) = \sum_{k=1}^K \alpha_{ik}(f) \exp\{x_k(f)\} + \epsilon_i(f) \quad (i=1, \dots, 2N) \tag{8}$$

where, the subscripts $i=1$ to N denote real parts and $i=N+1$ to $2N$ denote imaginary parts of the complex numbers ϕ_i , $\alpha_{i,k}$ and ϵ_i ,

$$N = M \times (M+1) / 2; \quad M: \text{Number of the wave probes} \tag{9}$$

$$\alpha_{i,k}(f) = \Delta\theta H_m(f, \theta_k) H_n^*(f, \theta_k) [\cos\{k(x_{mn} \cos \theta_k + y_{mn} \sin \theta_k) - i \sin\{k(x_{mn} \cos \theta_k + y_{mn} \sin \theta_k)\} / \sqrt{\Phi_{mm}(f)\Phi_{nn}(f)}] \tag{10}$$

$$\phi_i(f) = \Phi_{mn}(f) / \{S(f) \sqrt{\Phi_{mm}(f)\Phi_{nn}(f)}\} \tag{11}$$

$$\epsilon_i(f) = \epsilon_{mn}(f) / \sqrt{\Phi_{mm}(f)\Phi_{nn}(f)} \tag{12}$$

In Eq.(8), though ϕ_i , $\alpha_{i,k}$ and ϵ_i are the functions of the frequency f , f is omitted to simplify the expression hereafter.

When ϕ_i ($i=1, 2, \dots, 2N$) are given and ϵ_i ($i=1, \dots, 2N$) are assumed to be independent from each other and have the probability of their occurrence expressed by the normal distribution having the mean 0 and the variance σ^2 , the likelihood function of x_k ($k=1, \dots, K$) and σ^2 is given by Eq.(13).

$$L(x_1, \dots, x_K; \sigma^2) = \frac{1}{(2\pi\sigma^2)^{2N}} \exp\left[-\frac{1}{2\sigma^2} \sum_{i=1}^{2N} \left\{ \phi_i - \sum_{k=1}^K \alpha_{i,k} \exp(x_k) \right\}^2\right] \tag{13}$$

In the derivation of the equations mentioned above, the directional spreading function $G(\theta|f)$ is expressed by a piecewise constant function and the correlation between the wave energy falling on each segment of θ has not yet been taken into account considering the background of the linear wave theory. However, it is not unreal to assume that the energy distribution over the wave directions is discontinuous. Therefore, the additional condition must be added. As the simplest additional condition, the following condition is added by assuming that the second order difference of $\{x_k\}$ are close to zero for $k=1, \dots, K$. That is,

$$\sum_{k=1}^K \{x_k - 2x_{k-1} + x_{k-2}\}^2 \quad (x_0 = x_K, x_{-1} = x_{K-1}) \quad (14)$$

becomes smaller as the estimate of the directional spreading function $G(\theta | f)$ becomes smoother.

The estimate of x_k maximizing the likelihood (Eq.(13)) and minimizing the above mentioned quantity are determined as the estimates which maximize the following quantity :

$$\ln L(x_1, \dots, x_K; \sigma^2) - \frac{u^2}{2\sigma^2} \sum_{k=1}^K (x_k - 2x_{k-1} + x_{k-2})^2 \quad (15)$$

where, u^2 is a hyperparameter.

The maximization of Eq.(15) is achieved by maximizing the following exponential function having the power expressed by Eq.(15).

$$L(x_1, \dots, x_K; \sigma^2) \exp\left\{-\frac{u^2}{2\sigma^2} \sum_{k=1}^K (x_k - 2x_{k-1} + x_{k-2})^2\right\} \quad (16)$$

When normalized, the second term can be regarded as a following distribution of $\mathbf{x} = (x_1, \dots, x_K)$.

$$p(\mathbf{x} | u^2, \sigma^2) = \left(\frac{u}{\sqrt{2\pi}\sigma}\right)^K \exp\left\{-\frac{u^2}{2\sigma^2} \sum_{k=1}^K (x_k - 2x_{k-1} + x_{k-2})^2\right\} \quad (17)$$

In Bayesian statistics, the distribution $p(\mathbf{y} | \mathbf{x})$, which is called the posterior distribution, is proportional to the likelihood $L(\mathbf{y} | \mathbf{x})$ and the distribution $p(\mathbf{y})$, which is called the prior distribution, as follows.

$$p(\mathbf{y} | \mathbf{x}) \propto L(\mathbf{y} | \mathbf{x}) p(\mathbf{y}) \quad (18)$$

Thus, the distribution of Eq.(17) corresponds to the prior distribution in Bayesian statistics. The estimate of \mathbf{x} obtained by maximizing Eq.(16) is regarded as the mode of the posterior distribution of $p_{\text{post}}(\mathbf{x} | u^2, \sigma^2)$.

If the value of u is given, the value of \mathbf{x} which maximizes Eq.(18) are determined by minimizing Eq.(19), regardless of the values of σ^2 .

$$\sum_{i=1}^{2N} \left\{ \phi_i - \sum_{k=1}^K \alpha_{i,k} \exp(x_k) \right\}^2 + u^2 \left\{ \sum_{k=1}^K (x_k - 2x_{k-1} + x_{k-2})^2 \right\} \quad (19)$$

The most suitable values of the hyperparameter u^2 and the variance σ^2 are determined so that the following ABIC is minimum.

$$\text{ABIC} = -2 \ln \int L(\mathbf{x}, \sigma^2) p(\mathbf{x} | u^2, \sigma^2) d\mathbf{x} \quad (20)$$

4. NUMERICAL COMPUTATION OF DIRECTIONAL SPECTRUM

In order to estimate the directional spectrum by means of the Bayesian approach, the minimization of Eq.(19) and the integration and the minimization of Eq.(20) must be performed. The following is the summary of the procedure of the computation presented by Ishiguro (1985) and Sakamoto (1985).

- 1) For a proper value of hyperparameter u and initial values x_0 of x , compute the estimate of \hat{x} by means of the least square method utilizing Eq.(21).

$$J(x) \cong |\hat{A}x - \hat{B}|^2 + u^2 |Dx|^2 \tag{21}$$

where,

$$\hat{A} = AE(x_0) \tag{22}$$

$$\hat{B} = B - AF(x_0) + AE(x_0)x_0 \tag{23}$$

$$A = \begin{bmatrix} \alpha_{1,1}, & \dots, & \alpha_{1,K} \\ \vdots & & \vdots \\ \alpha_{2N,1}, & \dots, & \alpha_{2N,K} \end{bmatrix} \tag{24}$$

$$B = (\phi_1, \dots, \phi_{2N})^t \tag{25}$$

$$D = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 & 1 & -2 \\ -2 & 1 & 0 & \dots & 0 & 0 & 1 \\ 1 & -2 & 1 & \dots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 1 & -2 & 1 \end{bmatrix} \tag{26}$$

$$E(x) = \begin{bmatrix} \exp(x_1) & 0 & \dots & 0 \\ 0 & \exp(x_2) & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \exp(x_K) \end{bmatrix} \tag{27}$$

$$F(x) = \{\exp(x_1), \dots, \exp(x_K)\}^t \tag{28}$$

That is, for a certain initial value x_0 , the values of x_1 are computed by means of the least square method utilizing Eq.(21) through Eq.(23). Substituting these x_1 for the initial x_0 in Eq.(22) to Eq.(23), and repeating the same process, we obtain the another set of x_2 . Iterating these process until the values of x converges to \hat{x} , the estimate of \hat{x} is obtained for the given value of u^2 .

- 2) Compute the ABIC by Eq.(29) for the given u and the estimate of \hat{x} obtained above.

$$ABIC = 2N \ln(2\pi) + 2N + 2N \ln(\hat{\sigma}^2) - K \ln(u^2) + \ln\{\det(\hat{A}^t \hat{A} + u^2 D^t D)\} \tag{29}$$

where,

$$\hat{\sigma}^2 = \frac{1}{2N} \{|\hat{A}\hat{x} - \hat{B}|^2 + u^2 |D\hat{x}|^2\} \tag{30}$$

and \hat{A} and \hat{B} are the coefficient matrix renewed in Eq.(22) and (23), which are computed for the least square estimate \hat{x} .

- 3) Changing the value of u , repeat the process of 1) and 2).
- 4) From various estimates of \hat{x} obtained through the process 1) through 3), choose the values \hat{u}^2 and $\hat{\sigma}^2$ as well as the estimate \hat{x} which yield the minimum ABIC as the final estimate of x as the estimate of the directional spreading function.

In the computation of the estimate of the directional spreading function mentioned above, the initial values of x_0 are given uniformly ($x_i = \ln(1/2\pi)$). The iteration of Eq.(21) is terminated when the standard deviation of the difference between the values of x_n of n-th step and that of the previous step is smaller than or equal to 10^{-3} , i.e., $|\sigma_n| \leq 10^{-3}$.

In addition, the hyperparameter which minimizes the ABIC is found by the method of trial and error. The value of the hyperparameter is given by utilizing Eq.(31) with the value of m changing in a sequential manner.

$$u = ab^m \quad (m=1, 2, \dots) \quad (31)$$

The derivation of the Eq.(21) through Eq.(30) and the details of the computation is given in Hashimoto et al.,(1987).

5. EXAMINATION OF THE ESTIMATION METHOD BY NUMERICAL SIMULATION

5.1 procedure of numerical simulation

Numerical simulations were performed to examine the validity of the proposed method. The procedure is the same as the one used for examining the EMLM (Isobe et al.,1984).

The directional spectrum is expressed as a product of the directional spreading function and the frequency spectrum and is computed frequency by frequency. Hence, in this section, a directional spreading function for an arbitrarily chosen frequency is examined. The practical procedure of the numerical simulation is as follows.

- 1) The directional spreading functions to be employed in the examination are Mitsuyasu-type ones which are given by Eq.(32).

$$G(\theta) = \sum_i \alpha_i \cos^2 S_i \left(\frac{\theta - \theta_i}{2} \right) \quad (32)$$

where α_i is the proportionality coefficient and is given so that Eq.(32) satisfies Eq.(3). For the simulation of a uni-directional sea, the directional spreading function is given by Eq.(32) with $i=1$ only. On the other hand, for a bi-directional sea, two different wave groups having different values of α_i, S_i, θ_i ($i=1, 2$) are superimposed.

- 2) The cross-power spectra are computed for the directional spreading function given by process 1) utilizing Eq(1).
- 3) On the basis of the cross-power spectra obtained above, the directional spreading function is estimated by means of the methods mentioned in the previous section. The estimate of the

directional spreading function is compared with the input directional spreading function, i.e. the one given by Eq.(32).

In addition, the directional spreading functions are also estimated by the EMLM for the comparison of those given by the Bayesian approach.

5.2 Examination of the estimation method

The results of the simulations are shown in Fig.1 for the three types of arrays of wave probes. The same wave condition is employed for all the arrays : wind waves characterized by $S=10$ coming in the direction $\theta_1=0^\circ$ and a swell characterized by $S=100$ coming in the direction $\theta_2=100^\circ$ coexist, and the ratio of the peak spectral density of the two wave groups is $a_1/a_2=0.5$. In addition, the distance between the wave probes D is given as $D/L=0.2$ (L is the wave length of the component wave to be examined) for all the arrays. The solid lines denoted by TRUE in Fig.1 show the input directional spreading function, and the lines denoted by BDM shows the estimate of the directional spreading function given by the Bayesian directional spectral estimation method (which is called BDM hereafter). The ordinate of Fig.1 is normalized utilizing the peak value of the TRUE directional spreading function for respective cases as reference value.

It is observed in Fig.1 by comparing the estimates of the directional spreading functions result from Type-1 through Type-3 that as the number of wave probes increases, the directional resolution shown by the BDM and the EMLM is improved. In particular, the BDM for Type-2 and Type-3 are almost the same as the TRUE. On the other hand, though the EMLM seems to be closer to the TRUE than the BDM for Type-1 layout, the EMLM yields an erroneous peak inbetween the two peaks exhibited by the TRUE for Type-2 layout. The EMLM is considerably improved for Type-3 in comparison with the estimate for Type-2, but the resolution is inferior to that of the BDM. For the wave probe arrays consisting more than or equal to four probes, it is seen that the BDM shows a better directional resolution than that of the EMLM.

Fig.1 Directional spreading functions estimated from various types of probe arrays

For Type-1 layout, only three wave probes are utilized to measure the directional seas, the BDM does not find a suitable statistical model to explain directional seas. The reason is supposed that three independent wave properties are the minimum data to analyze the directional spectrum, and so it is impossible to estimate the errors introduced in Eq.(8).

The effect of the errors contained in the cross-power spectral estimates is illustrated in Fig.2 for six different magnitudes of errors. The probe array employed is Type-2. The values of r in the figure show the ratio of the magnitude of the errors added to the cross-power spectra and the absolute values of the cross-power spectrum. In the computation, the same magnitude of errors is equally added to all the four wave properties.

It is noted that as the magnitude of error increases, the information of the directional spectrum carried by the cross-power spectra become more biased. In fact, as seen in Fig.2, the estimates of the BDM become flatter as the magnitudes of errors increases. On the other hand, when the cross-power spectra contain larger errors, the EMLM estimates erroneous peaks and sometimes fails to yield a smooth and continuous estimates of directional spreading function. However, in these cases, the BDM detects the directional peaks properly, though it underestimates the peak values. Thus, the BDM seems to be very robust method against the errors.

6. FIELD DATA ANALYSIS

6.1 Facilities of directional wave measurement

The new method for the estimation of directional spectrum on the bases of the Bayesian approach mentioned above is applied to the analysis of the wave records acquired at an offshore oil rig 42 km off the Iwaki coast (Northeastern coast of the main island of Japan, see Fig.3). The Onahama Port Construction Office (OPCO), the Second Port Construction Bureau, Ministry of Transport, is conducting a multi-element measurement of ocean waves at this location. Figure 4 shows

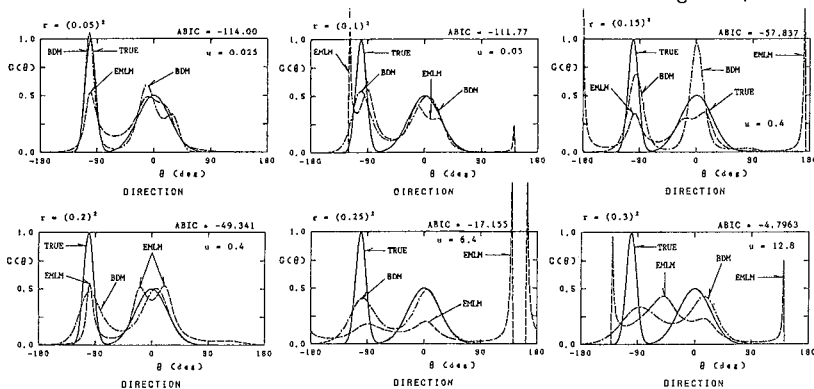

Fig.2 Effect of noise in cross-power spectra on the estimates of directional spreading functions

Fig.3 Location of the observation station

Fig.4 Offshore oil rig and the location of wave probes

Fig.5 Wave probe array

the oil rig where four step type wave gauges and a two-axis directional current meter with a pressure sensor are installed on its legs as shown in Fig.5. The location of the rig is $37^{\circ} 17' 49''$ N and $141^{\circ} 27' 47''$ E, in a water depth of 155m below C.D.L.

The simultaneous measurement of 7 elements is performed for 20 minutes at a time interval of two hours. The wave records as well as the wind records are immediately transmitted by a radio telemetering system to a nearby coastal relay station for landline transmission to the OPCO.

The time series wave data are recorded on a digital magnetic tape. Data are also analyzed immediately following each observation using a mini-computer of the OPCO for real time information such as significant wave height, wave period and mean wave direction, etc. The EMLM is employed for the real time directional analysis at the office. The directional wave analysis presented herein is performed at the Port and Harbour Research Institute using the wave data recorded on the magnetic tapes.

6.2 Field data analysis

The time series wave records analyzed here were obtained during the passage of Typhoon No.17 from September 29 to 30 in 1986. At 12:00 on September 30, the maximum significant wave height ($H_{1/3} = 6.20\text{m}$) and period ($T_{1/3} = 12.5\text{s}$) was recorded. Figure 6 is the weather maps of these two days.

Figure 7 shows the time variation of the directional spectrum estimated on the basis of the 7-element wave records by the BDM for every four hours from 16:00 on Sept. 29 to 20:00 on Sept. 30. Up to 4:00 on Sept. 30, bi-directional seas are observed: swell comes from the south and the wind generated waves come from the east-southeast at the same time. After 8:00 on the 30th, the directional spectra are uni-directional. During the passage of Typhoon No. 17, the significant wave height shows two maxima. One was observed at 2:00 on the 30th, when the spectral density of the swell reaches its maximum. The other peak significant wave height was observed at 12:00 on the 30th and it was the highest during these two days. It should be noted that the directional spreading of the directional spectra observed at 12:00 and later are constricted at the peak frequency, i.e., the concentration of the spectral density is highest at the peak frequency and becomes lower as the frequency deviates from the peak frequency. This is the same characteristics shown in the directional spreading function proposed by Mitsuyasu et al.(1975).

Examples of the directional spectra for various types of probe arrays estimated by the BDM and the EMLM are compared in Fig.8. The left figures are the estimates given by the BDM and the right figures are those by the EMLM. The major difference between the estimates given by the two different methods is that those given by the BDM show higher spectral peak than those given by the EMLM. Though the BDM yields almost the same shape of the directional spectral estimates for various types of probe arrays, the EMLM yields the different shape of the estimates depending on the arrangement and the number of wave sensors.

On the basis of these results, we conclude that the estimates of the directional spectra show considerably different shapes depending

on the method for the directional spectral estimation. Therefore, many wave properties must be measured, and the estimation method utilized must be examined for a detailed analysis of the directional spectrum.

6. CONCLUSIONS

The following major conclusions sum up the study:

- 1) The proposed Bayesian Directional Spectral Estimation Method (BDM) can be applied for the directional wave analysis on the basis of an arbitrary wave probes. However, the method needs wave records consisting of at least four elements of wave properties. When only three elements are measured, the Extended Maximum Likelihood Method (EMLM) and the Maximum Entropy Principle Method (MEP : Kobune and Hashimoto ; 1986) are recommended.
- 2) When four or more wave probes are employed in the observation, the BDM is the preferred analytical approach. The directional resolution exhibited by the BDM in this circumstance is greater than those shown by the EMLM or other existing methods.
- 3) The BDM is fairly sound against the noises contained in the estimates of the cross-power spectra. As the rate of the noise over the cross-power spectra increases, the estimate given by the BDM becomes flatter than the true directional spectrum. This BDM tendency emerges as the method tends to rely on the a priori condition (smooth and continuous), whenever the given information (cross-power spectra) is not reliable enough. When the cross-power spectra contain large errors, the EMLM fails to yield reasonable estimates, while the BDM can detect the directional peak where the true directional spectrum shows its peak density.
- 4) Estimates of the directional spectrum vary widely depending on the method employed for the directional wave analysis, number of elements of wave properties to be analyzed and the layout of the probes. Though the directions where the directional spectrum shows its peak density can be detected from the directional wave analysis on the basis of three or four element measurement, it is necessary to measure directional waves with many probes to detail the shape of the directional spectrum. For field observation, especially in deep sea, simultaneous measurements of many wave properties are very difficult for technical and financial reasons. However, the BDM is a very powerful method for the directional wave analysis in laboratories.
- 5) In the present paper, as an a priori condition, the simplest condition is introduced to characterize the inherent nature of the directional spectrum. This is necessary, as the BDM relies heavily on the a priori condition when the given information is insufficient, to delineate the directional spectrum. However, when research reveals more detail in the structure of ocean directional waves, the method can be improved by adopting the newly attained knowledge as the a priori condition. Thus, the BDM is more adaptable to reformulation of the estimation equations as the study of structures of directional wave spectrum progresses.

CHAPTER 5

Longshore Current Forcing at a Barred Beach

D.J. Whitford¹ and E.B. Thornton², Member ASCE

1. Introduction

A local alongshore momentum balance was measured at various locations across a barred surf zone during the SUPERDUCK experiment held at the U.S. Army Corps of Engineers, CERC Field Research Facility (FRF), DUCK, N.C., U.S.A. on October 16, 1986. A mobile sled was instrumented to measure the various terms in the alongshore momentum equation. Numerically orienting the instrumentation perpendicular to the local bottom contours, the alongshore momentum balance simplifies to:

$$\frac{\partial M_y}{\partial t} + \frac{\partial S_{yx}^T}{\partial x} = \tau_y^n - \tau_y^b \quad (1)$$

where the terms represent (left to right) the temporal change of the time-averaged, depth-integrated mean momentum per unit area in the alongshore direction (M_y) due to both steady (\bar{M}_y) and unsteady (M_y') flow, the cross-shore gradient of the total alongshore momentum flux, surface wind stress, and bottom shear stress.

Three vertically and horizontally separated Marsh-McBirney bi-directional electromagnetic current meters, a Paroscientific digiquartz pressure sensor, and a single-point R.M. Young wind monitor, all mounted on a moveable sled, were used to measure current, wave and wind conditions in the surf zone. Spatially-dependent bed shear stress coefficients were determined as residuals from the alongshore momentum balance.

2. Experimental Site

The FRF site is located along a 100-km unbroken stretch of barrier island formation known as North Carolina's "Outer Banks." There are no littoral barriers to perturbate incoming wave trains along the entire reach of shoreline. The site has a tidal range of 0.5 to 2.0 m and regular offshore bathymetry. On October 16, the beach had a mean foreshore slope of 0.06, a single alongshore linear bar system, and a mean slope of 0.02 offshore of the

²Naval Postgraduate School, Monterey, CA, 93943 U.S.A.

bar.

Sled instrumentation and deployment were described in Martens and Thornton (1987). Current meters were mounted at approximately 0.5 m, 1.0 m, and 1.5 m above the sled bottom. A Paroscientific digiquartz pressure sensor was used to infer surface elevation and mean water depth.

Daily bathymetric profiles of the experiment site were accurately measured with a Zeiss Elta-2 laser surveying system which sighted on the FRF Coastal Research Amphibious Buggy (CRAB) as it methodically traversed the experiment area. Precise orientation of the sled was achieved to within 0.5° using the laser surveying system to triangulate on two reflective prisms mounted approximately 2 m apart on a mast spreader above the sled.

Sled sensor measurements were acquired during 9 transects of the surf zone over a 7-day period. This paper discusses only a single transect accomplished on 16 October, as the additional transects are currently undergoing analysis. Wind speeds measured at 10 m elevation ranged from 10 to 12 ms⁻¹ and offshore H_{mo} ranged from 1.4 to 1.6 m. The transect consisted of 5 positions across the surf zone - outside the surf zone, at the point of maximum wave breaking, immediately before the bar, on top the bar, and in the bar-trough. Data were acquired at each position for approximately 35 minutes.

3. Momentum Balance Term Formulation

a. Temporal variability of mean longshore currents - Mean alongshore momentum is formulated from:

$$M_y = \overline{M_y} + M_y' = \rho V D + \int_{-h}^{\eta} \rho v' dz \quad (2)$$

where ρ is water density, V and v' are the mean and fluctuating components of the longshore current, D is the mean water depth, η is sea surface elevation and the over-bar denotes time averaging. Finite differencing in time was examined by varying the time step from 1-22 minutes, with and without a running mean.

b. Cross-shore gradient of alongshore momentum flux - Alongshore momentum flux (or radiation stress) is calculated using a linear wave theory transfer function:

$$S_{yx}(f) = |H(f)|^2 C_{uv}(f) \quad (3)$$

$$|H(f)|^2 = \frac{\rho[\sinh(2kh) + 2kh]}{4k[\cosh^2 k(h + z_m)]}$$

where C_{uv} is the co-spectrum of the current velocity components (u, v), f is frequency, k is wavenumber, h is mean water depth, and z_m is the measurement depth. Finite differencing in space is taken over the horizontal

distance between sled run positions, varying between 13-51 m. S_{yx}^T is the summation of $S_{yx}(f)$ over the sea-swell frequency band (0.06-0.44 Hz).

c. Surface wind stress -The alongshore component of surface wind stress (τ_y^N), hereafter referred to as simply 'surface wind stress', is calculated using the drag coefficient method (also called the bulk coefficient method):

$$\tau_y^N = \rho_a C_{d10} |U_{10}| U_{10y} \quad (4)$$

where ρ_a is air density, C_{d10} is a stability-dependent atmospheric drag coefficient for an elevation of 10 m, and U_{10} and U_{10y} are the total and alongshore components of wind speed measured by the sled anemometer, with atmospheric stability conversion to $z = 10$ m. During the SUPERDUCK experiment, Sethu Raman et al. (1987) calculated wind stress (τ^N) by the eddy correlation method using a three-component Gill anemometer. The wind speed measurements were acquired for $z_m = 18.7$ m at the seaward end of the FRF pier. This location was outside the surf zone and approximately 400 m from the sled transect area. Relative humidity, air, and sea surface temperature were also measured at the seaward end of the FRF pier. Atmospheric friction velocity (u_*) and the Monin-Obukhov length (L) were assumed spatially constant over both the surf zone and the end of the FRF pier. Onshore winds and unstable atmospheric conditions were predominant during the sled transect. A stability-dependent drag coefficient for the end of the FRF pier at a height of 10 m was calculated using:

$$u_* = (\tau^N / \rho_a)^{1/2} \quad (5)$$

$$U_{10} = U_{zm} - \frac{u_*}{\kappa} \left[\ln \frac{z_m}{10} + \psi_m \left(\frac{10}{L} \right) - \psi_m \left(\frac{z_m}{L} \right) \right] \quad (6)$$

$$C_{d10} = \tau^N / [\rho_a (U_{10} - U_0)^2] \quad (7)$$

where $\kappa = 0.4$ is von Karman's constant, ψ_m is an integral diabatic term for momentum, U_0 is the mean current (assumed negligible at the end of the FRF pier), and L is determined from the Businger et al. (1971) iterative approach. The increased surface roughness of a surf zone may be conservatively likened to the chaotic seas observed in advance of a cold front. Swell generated behind the cold front can travel through the front and interact with waves generated ahead of the front and propagating parallel to the front. This interaction results in a chaotic sea of larger, steeper waves and enhanced wave breaking. From a composite of wind stress measurements taken from multiple chaotic sea cases found in advance of storm fronts, the atmospheric drag coefficient was found to be increased by approximately 33% over that expected for non-chaotic seas of equal windspeed (Davidson et al., 1988a, 1988b). Atmospheric drag coefficients for the surf zone are therefore increased by

33% over that determined for the end of the FRF pier. Surf zone surface wind stress is then calculated from eqn. (4) and (6), where the C_{d10} and U_{10} are for the sled location. The substitution of $U_{10}-U_0$ for U_{10} in eqn. (4) for the surf zone surface wind stress made negligible difference.

d. Bottom shear stress - Bottom (or bed) shear stress is determined as the residual in eqn. (1). A bed shear stress coefficient (C_f) is then determined from:

$$C_f = \frac{\tau_b}{[\rho(u^2 + v^2)^{1/2}v]} \quad (8)$$

4. Sled Operation

The sled was deployed in an area of straight-and-parallel isobaths. The sled was towed offshore by the FRF's CRAB and dragged onshore with a tethered chain by a heavy-duty forklift. The sled's position and orientation were determined from laser surveys acquired at the beginning and end of each data run, with additional positioning surveys acquired during the run itself. Prior to sled deployment, a portable Zeiss laser ranging system was used to precisely determine the sled instruments' three-dimensional coordinates with respect to the sled prisms' three-dimensional coordinates. Laser surveys of the sled mast prisms during sled deployment provided precise location, sled pitch angle, and sled yaw angle to correct the sensor data with respect to the local horizontal and vertical. A mean bathymetric isobath orientation is determined by applying a least-squares regression fit to the bathymetric data. The sensors are then oriented with respect to this mean bathymetric isobath to determine cross-shore and longshore currents. Breaking waves were visually identified and electronically marked on the data tapes. The analog data were PCM encoded at the sled, telemetered ashore, decoded, and recorded on 9-track magnetic tape. The data were digitized at 8 Hz, demeaned and spectrally analyzed using Fast Fourier Transforms and ensemble averaging.

5. Data Analysis

Since S_{yx} is conserved outside the surf zone, any $S_{yx}(f)$ difference between the current meters measured outside the surf zone is assumed to be attributable to incorrect current meter alignment with respect to each other and the sled. Therefore, the rear current meter was numerically rotated until its $S_{yx}(f)$ coincided with the front current meter $S_{yx}(f)$. This 2.86° rotation was assumed to account for the alignment error and was fixed for the remaining data runs inside the surf zone.

Current meter calibration was conducted in flow tanks by different laboratories before and after the experiment. Current meter gain agreed within $\pm 3\%$ and current meter offset differed by only 0.01 - 0.04 ms^{-1} .

Homogeneity of surf zone currents is investigated by

overlying the bathymetry contours on both the mean current vectors determined at each sled run position and the mean current vectors determined from the fixed-bed current meters of an alongshore array (Figure 1). All current vectors have the same general direction and magnitude relative to their cross-shore position. No evidence of rip currents were seen visually during the sled transect nor are rip currents detected in Figure 1. Homogeneity of the surf zone current regime is therefore assumed for 16 October.

Stationarity is investigated by examination of S_{yx}^T calculated from measurements outside the surf zone acquired from a fixed-bed pressure and velocity sensor designated 'south tripod.' Sequential 34.1-minute spectra are calculated and resultant S_{yx}^T versus time are compared to the sled run transect times (Figure 2). In shallow water, $S_{xy} = \rho h \text{cov}_{uv}$. Ninety-five percent confidence limits for S_{yx}^T in Figure 2 are based on the Fisher-Z transformation (Miller and Freund, 1985):

$$Z = \frac{1}{2} \ln \left[\frac{1+r}{1-r} \right] \quad (9)$$

where the correlation coefficient (r) is

$$r = \frac{\text{cov}_{uv}}{\sigma_u \sigma_v} \quad (10)$$

and σ_u , σ_v are the standard deviations of u and v , and the covariance is calculated by integrating the co-spectrum of u , v . The Fisher-Z statistic is a value of a random variable having approximately a normal distribution. Unfortunately the 'south tripod' gage was not recording for the entire time of the transect. Therefore, stationarity is confirmed only for the first two runs of the transect and is assumed for the last three runs.

Relative contributions of wave forcing ($\partial S_{yx}^T / \partial x$), wind forcing (τ_y^n), and temporal variability of mean momentum ($\partial M_y / \partial t$) to the total momentum balance are determined by first defining their total contribution (TOT) as the cumulative sum of their absolute values:

$$\text{TOT} = \left| \frac{\partial S_{yx}^T}{\partial x} \right| + \left| \tau_y^n \right| + \left| \frac{\partial M_y}{\partial t} \right| \quad (11)$$

Their individual relative contributions (rc) are then determined by dividing by the total contribution:

$$\text{wave}_{rc} = \frac{\left| \frac{\partial S_{yx}^T}{\partial x} \right|}{\text{TOT}} \quad (12)$$

Figure 1. Sled and alongshore array mean current vectors for 16 October 1986 overlaid on bathymetry. Velocity scale is at upper right.

Figure 2. Offshore S_{yx} spectra and S_{yx}^T from 'puv' gage 621 for October 1986. Three representative S_{yx} spectra are shown. Numbers on S_{yx}^T figure indicate data runs. Intervals are 95% Fisher-Z confidence.

$$\text{wind}_{rc} = \frac{|\tau_y|}{TOT} \quad (13)$$

$$\frac{\partial M_y}{\partial t}_{rc} = \frac{\left| \frac{\partial M_y}{\partial t} \right|}{TOT} \quad (14)$$

An error analysis was conducted to place error bounds on the bed shear stress coefficients. Errors considered were beach angle orientation error, measurement error, finite differencing error, and an estimate of unquantified errors.

6. Results

Measured data and calculated results for all five data runs on 16 October are listed in Table 1. Three-dimensional portrayal of the mean current structure across the bar is illustrated in Figure 3. Current vectors represent 34.1-minute means and the numbers label data run locations. The short dotted lines above each run location indicate the mean water level (MWL) for each run and the long dashed line indicates mean sea level. The different arrowheads represent the three different current meter heights above the bed. Runs 16-4 and 16-5 had only two current meters totally submerged due to their shallow locations. The onset of breaking occurs between Runs 16-2 and 16-3.

Mean alongshore current [$0(1.0 \text{ ms}^{-1})$] dominates over the mean cross-shore current [$0(0.1 \text{ ms}^{-1})$]. Significant spatial variability is observed across the bar with strongest flow just before the bar and weakest flow in the trough and outside the breaker zone. The spatial distribution of the longshore current is of the same order as that found by Thornton and Guza (1986) for a planar beach, and thus the bar appears not to exert any major perturbation on the spatial variability of the flow from the trough to offshore. No measurements were taken inside the foreshore breakers where an additional peak (although of smaller magnitude) in mean longshore current would be expected. The substantial flow in the trough may be due to an along-shore pressure gradient (which was not measured) or turbulent mixing, since there was essentially no wave breaking occurring inside the trough between Runs 16-5 and 16-6. The current outside the breaker zone may be attributable to turbulent mixing. Offshore flow near the bed is noted for Runs 16-4 through 16-6. The vertical distribution of alongshore and cross-shore velocities is compared to normalized water depth (Figure 4). Current measurements for a single run are connected, with the numbers indicating the chronological run order (i.e., number 1 is run 16-2). Nearly depth-uniform flow is seen for the mean alongshore current, with a slight increase in velocity near the surface. A logarithmic velocity profile between current meter heights (0.5-1.5 m) was not found. However the data does not preclude a logarithmic profile over a different height

Figure 5. Bed shear stress coefficients (C_f) and percent breaking wave (Q) values as a function of offshore distance (C_f is above and Q is below the profile line).

interval (e.g., 0.0-1.0 m). The mean cross-shore flow exhibits a tendency for onshore flow in the upper third of the water column and offshore flow in the lower third of the water column.

The mean momentum due to the waves (M_y') was found to be less than an order of magnitude of the mean momentum due to the steady flow (M_y). Varying the time step for the temporal term (as discussed in paragraph 3a) made negligible difference, therefore Δt was arbitrarily assigned as 64 seconds.

Spatially-variable bed shear stress coefficients, calculated for the distance between run positions, and the percentage of waves which were breaking at each run position are indicated above and below the bathymetric profile in Figure 5. The bed shear stress coefficients are of $O(10^{-3})$ and are of the same order of magnitude as the model-fitted C_f values determined by Thornton and Guza (1986) using a non-linear formulation for bed shear stress. Spatial variability is indicated with higher C_f values offshore the bar and lower C_f values immediately before and on the bar. Grant et al. (1984) showed that C_f is increased by a factor of 2-3 due to the combined effect of waves and currents, therefore the shoreward decreasing C_f may be attributed to the shoreward decreasing surface wave action.

A surprising result was the low percentage of waves which were visually identified and marked as breaking waves. Visual identification of breaking was defined as when "white water" was observed passing the sled mast. For example, Run 16-3 was visually positioned in the surf zone at the point of maximum breaking (i.e., where the breaking wave heights were largest and therefore the maximum wave dissipation was occurring), yet only 12% of the waves were identified as breaking. Subsequent runs exhibited even less breaking wave occurrences.

The relative contribution of the radiation stress gradient to the momentum balance is observed to be highest at the two locations of maximum wave breaking - just before the bar (Run 16-3) and near the foreshore (Run 16-6). Surface wind stress' relative contribution doubles to nearly 20% in the trough, where wave breaking is reduced. The relative contribution of the temporal term increases shoreward from approximately 3% to a maximum of nearly 20% in the trough, perhaps due to the effect of infra-gravity waves and decreased wave breaking.

7. Summary

A local alongshore momentum balance is calculated from measurements of pressure, current, and wind acquired during a single transect of a barred beach during the SUPERDUCK experiment. Large incident wave angles (10° - 19°), combined with a highly accurate laser surveying system, signifi-

cantly reduced S_{yx} angular sensitivity which had plagued previous nearshore investigations and precluded accurate S_{yx} calculations. Surface wind stress is calculated using a stability-dependent atmospheric drag coefficient determined from wind stress measurements acquired during the field experiment. A three-dimensional depiction of surf zone currents indicates nearly depth-uniform mean alongshore flow with a slight increase in alongshore flow near the surface. Mean cross-shore flow indicates a tendency for onshore flow in the upper water column with offshore flow in the lower water column. Significant spatial variability of the alongshore flow is observed with maximum flow immediately offshore the bar. Spatial variability of the bed shear stress coefficient is observed with larger values offshore the bar (0.003-0.004) and lower values on the bar and in the trough (0.001). Relative contributions of wind forcing and the temporal term to the alongshore momentum balance are less than 10% offshore of the bar, where wave forcing was largest. However, relative contributions of wind forcing and the temporal term both approach 20% on the bar and in the trough. For this data set, wind forcing and the temporal term were not negligible terms in the momentum balance for locations on the bar and in the trough.

The information presented is the result of a single transect of the barred beach. A much more definitive conclusion should be reached after analysis of the remaining 8 transects of SUPERDUCK data.

8. Acknowledgments

Support for this field investigation and analysis was received from ONR under Contract NR 388-114. The staff of the U.S. Army Corps of Engineers, CERC Field Research Facility, Duck, N.C., assembled the sled and installed and maintained the offshore sensors and data acquisition system for the SUPERDUCK experiment.

CHAPTER 6

NUMERICAL COMPARISON OF WAVE SYNTHESIS METHODS

M.D. Miles¹ and E.R. Funke¹

ABSTRACT

A numerical comparison study is carried out on a variety of methods for synthesizing pseudo-random Gaussian wave records for laboratory wave generation. Three nonharmonic superposition methods and three time domain filtering procedures are compared to a harmonic FFT technique. The synthesis methods are evaluated on the basis of a statistical analysis of 16 standard wave parameters obtained from a set of 200 wave records. Second order group-bounded long wave components are also investigated.

INTRODUCTION

Numerically synthesized wave records are commonly used to drive wave machines in laboratory basins in order to produce reasonably realistic simulations of the wind generated seas found in nature. A variety of numerical techniques have been used as described in Funke and Mansard (1987). These are all based on the assumption that natural seas can be modelled as a stationary, ergodic, Gaussian random process. Although this assumption becomes questionable in extreme wave conditions, linear synthesis methods have generally proven to be practical tools in many coastal and ocean engineering applications. The relative advantages and limitations of various linear simulation models are discussed in Medina et al. (1985).

Some methods are popular because they are believed to be superior representations of a natural sea state due to their ability to generate arbitrarily long non-repeating wave records with continuous rather than discrete spectra. Others are promoted on the basis of computational efficiency. FFT techniques can efficiently handle a large number of frequencies and are also very convenient for operations such as phase propagation and transfer function compensation. A potential disadvantage of the FFT approach is that it imposes the restriction that all components must be harmonically related. As a consequence, FFT wave records are always cyclic in contrast to nonharmonic methods. Since any constraint in a synthesis procedure may have an effect on the statistical

¹ Hydraulics Laboratory, National Research Council,
Ottawa, Ont., Canada, K1A 0R6

properties of the wave records, it was decided to carry out a numerical study to compare a standard FFT method with six different nonharmonic wave synthesis procedures.

The synthesis methods were compared by performing a statistical analysis of 16 basic wave parameters obtained from frequency and time domain analysis of a set of wave records generated by each method. Two different target spectral density functions were used and 200 independent wave records were computed for each wave spectrum and synthesis method. In order to cover both broad and narrow spectra, a Pierson-Moskowitz (PM) spectrum and a JONSWAP spectrum with $\gamma = 7$ were chosen as the two target spectral densities. Each target spectrum had a peak frequency of 0.55 Hz which is a typical frequency for model basin applications. The synthesized wave records had a duration of 200 seconds (model scale). The peak frequency and record length were chosen to be compatible with a previous study comparing different FFT synthesis methods (Mansard and Funke, 1986). At a scale of 1:36, the duration of the synthesized wave records corresponds to the 20 minute length which is typical of most full scale wave records. Each wave record thus contained approximately 100 wave cycles.

The synthesized wave records were analyzed for the following parameters:

- (1) FPD = peak frequency by the Delft method.
- (2) QP = Goda peakedness factor.
- (3) HMO = estimate of significant wave height = $4\sqrt{m_0}$.
- (4) m_1 = first spectral moment.
- (5) m_2 = second spectral moment.
- (6) m_3 = third spectral moment.
- (7) H13D = zero downcrossing significant wave height.
- (8) HMAXD = maximum zero downcrossing wave height.
- (9) HMAXD/H13D = ratio of maximum and significant zero downcrossing wave heights.
- (10) SZ[HSIG] = average steepness of the significant waves.
- (11) SCF[HSIG] = average crest front steepness of the significant waves.
- (12) MYH[HSIG] = average horizontal asymmetry factor of the significant waves.
- (13) RL[HAV] = average run length of a group for waves greater than the average wave height.
- (14) TRN[HAV] = average length of a total run for waves greater than the average wave height.
- (15) RL[HSIG] = average run length of a group for the significant waves.
- (16) TRN[HSIG] = average length of a total run for the significant waves.

Parameters 1-12 are defined in the "List of Sea State Parameters" published by the IAHR Working Group on Wave Generation and Analysis in January, 1986. The run length parameters (13-16) are defined in Goda (1976).

In order to give particular attention to the possibility that nonharmonic simulations may be necessary in order to correctly represent the long wave content, a shallow water depth of 0.5 m was assumed for which the theoretical group-bounded long wave components were calculated using the

methods described in Barthel et al. (1983). Since wave grouping is greater for narrower spectra, only the JONSWAP target spectrum was used for this part of the study. The length of the wave records was also increased from 200 to 400 seconds because of the low frequencies involved. The standard deviation, maximum and minimum elevations and average period were calculated for the long wave components.

A separate investigation was also carried out to determine how well typical wave records synthesized by the nonharmonic methods could be approximated by an equivalent FFT-based harmonic representation.

WAVE SYNTHESIS METHODS

Method M1:

The first nonharmonic technique used was the equal amplitude component superposition method (Borgman, 1969). In this procedure, the frequency density varies with spectral amplitude as shown in Figure 1. Although the wave records were actually synthesized with 200 components, only 66 components have been shown in Figure 1 for clarity. Each of the wave simulation methods was checked by computing the average measured wave spectrum for all 200 synthesized wave records and plotting this together with the target spectrum. The results for method M1 are shown in Figure 2. It can be

Fig.1 Method M1
Frequency Comb

Fig.2 Average Spectra of
Method M1 Records

seen that the method gives a very close fit over the main part of each spectrum but the lack of frequency density is evident in the high frequency tail above 1 Hz. This effect could be reduced by increasing the number of components but the computation time becomes prohibitive. In order to provide a uniform basis for comparison, it was decided to use 200 components for all of the nonharmonic superposition procedures in accordance with the recommended value for Method M2.

Method M2:

The second nonharmonic method used was the deterministic spectral amplitude technique defined in Goda (1970). This procedure uses a random distribution of frequencies whose average spacing increases with frequency. The amplitude of each component is set to a value such that the energy of the component is equal to the area of the target spectrum over the frequency band to be represented by the component. The phase of each component is selected at random from a uniform

distribution. Method M2 thus has deterministic amplitude combined with random frequency and phase.

Method M3:

The third nonharmonic superposition technique was the random amplitude and frequency method. This is essentially a modified version of the Random Fourier Coefficient FFT technique with randomized instead of harmonic frequencies. The frequency range is first partitioned into N intervals of constant width. A final set of N frequencies is then obtained by selecting one frequency at random from a uniform distribution over each interval. This method thus has random amplitude, frequency and phase.

Method M4:

The fourth nonharmonic method was the filtering of pseudo-random Gaussian white noise in the time domain using a linear nonrecursive filter. This method has the advantage that filters can be designed very quickly to match any desired target spectrum. It is necessary to use rather long filters in order to obtain a close fit to the target spectrum, however. Consequently, this method is not computationally efficient for generating large numbers of wave records.

The average measured spectra for the 200 wave records synthesized by this method are shown in Figure 3. It can be seen that a very close match was obtained for both target spectra. However, this required fairly long filters with 300 points for the PM spectrum and 1000 points for the JONSWAP.

Fig.3 Average Spectra of Method M4 Records

Fig.4 Typical Method M5 Wave Record

Method M5:

The fifth nonharmonic technique used was the filtered binary noise method which is also known as the Wallingford method (Fryer et al., 1973). This method is based on a digital pseudo-random binary noise generator which is implemented by means of a 65-bit shift register. The desired spectral shape is obtained by using a digital filter which computes a weighted sum of pairs of bits from the shift register. Although the shift register contains binary noise, the output signal is approximately Gaussian because of the summation process of the digital filter. This method is normally implemented in hardware but it was simulated in software for the present study. Figure 4 shows the raw output signal and the signal after low-pass filtering.

The average measured spectra for the 200 wave records generated by this method are shown in Figure 5. An excellent fit is obtained for the PM case but the peak of the average measured JONSWAP spectrum is somewhat lower and wider than the target. This is probably due to the fact that only 16 digital filter components are available to define the main part of the spectrum which is somewhat marginal for this narrow-band situation.

Fig.5 Average Spectra of Method M5 Records

Fig.6 Average Spectra of Method M6 Records

Method M6:

The sixth nonharmonic method investigated was the Autoregressive Moving Average or ARMA filter method. In this technique, Gaussian white noise is filtered in the time domain using an ARMA filter whose coefficients are selected to obtain the desired target spectrum. The use of ARMA filters for wave synthesis is discussed in Samii and Vandiver (1984) and Medina et al. (1985). ARMA filters are the most general class of linear digital filters. Their main disadvantage is that they are rather difficult to design for any given spectral shape. Once the ARMA coefficients have been determined, however, they are much more efficient than the nonrecursive filters used in method M4 because the number of terms required is much smaller.

A good fit to the PM spectrum was obtained with an ARMA(15,15) filter but it was necessary to use an ARMA(21,21) filter to fit the JONSWAP spectrum. The average measured spectra for this method are shown in Figure 6. The PM fit is excellent. The JONSWAP fit is also very good although the peak of the average measured spectrum is slightly lower than the target.

Method M7:

There are two basic FFT methods which are commonly used for wave synthesis. These are the Random Phase (RP) method and the Random Fourier Coefficient (RFC) method (Funke and Mansard, 1987). The RP method is spectrally deterministic whereas the RFC method is not. It was decided to use the RFC method for this study so that the statistical variability of the synthesized wave records would be commensurate with that of natural wave records of similar duration.

2048 frequency components were used with a frequency spacing of 0.005 Hz for the 200-second records. This resulted

in 4096-point wave records with $\Delta t = 0.0488$ seconds. The 400-second records for the long wave investigation were synthesized with $\Delta f = 0.0025$ Hz and $\Delta t = 0.0977$ seconds.

WAVE PARAMETER STATISTICS

Each set of 200 wave records synthesized by a particular method for a given target spectrum was analyzed in order to obtain values for the wave parameters defined previously. This resulted in a set of 200 independent samples for each parameter. A basic statistical analysis was then carried out on each set of parameter values in order to compare the performance of the different synthesis methods.

The resulting wave parameter statistics are plotted for comparison in Figures 7 and 8 for the PM and JONSWAP spectra respectively. The 90% confidence intervals have been calculated on the basis of a Gaussian distribution. The results of a Chi-squared goodness-of-fit test indicate that most of the parameters do have Gaussian distributions. HMAXD, HMAXD/H13D and the four run length parameters were found to be non-Gaussian, however. Consequently, the confidence intervals for these parameters must be considered as rough estimates only.

The filtered Gaussian white noise methods M4 and M6 do not impose any constraints on the basic assumption that the sea can be modelled as a stationary Gaussian process. Consequently, these methods would be expected to generate the most realistic wave records. Method M4 was selected as the primary benchmark against which the other methods were evaluated, because the nonrecursive filters were able to match the target spectra with greater precision than the ARMA filters used in method M6.

It can be seen from Figures 7 and 8 that there is generally good agreement on the mean values of the wave parameters obtained by the various synthesis methods. One exception is the third spectral moment where method M1 is biased slightly high and method M5 is biased slightly low. This occurs for both the PM and JONSWAP spectra and is probably caused by a lack of frequency density in the high frequency tail. The mean value of HMAXD is also slightly lower for method M5 compared to the other methods.

There are considerable differences in the standard deviations of certain parameters. Since methods M1 and M2 are spectrally deterministic, it is not surprising that the standard deviations of the spectral parameters and H13D are much smaller for these methods. The standard deviations of the wave steepness parameters are also somewhat smaller, but the variability of the other time domain parameters is not strongly influenced by the fact that methods M1 and M2 are spectrally deterministic.

One interesting feature of the results is that method M3 has substantially larger standard deviations than the other methods for all of the spectral parameters and also for H13D, SZ and SCF. This effect is most noticeable in QP for the PM spectrum where the mean is also biased high. Since method M3 is simply a randomized frequency version of the FFT method, it was suspected that this effect might be caused by an

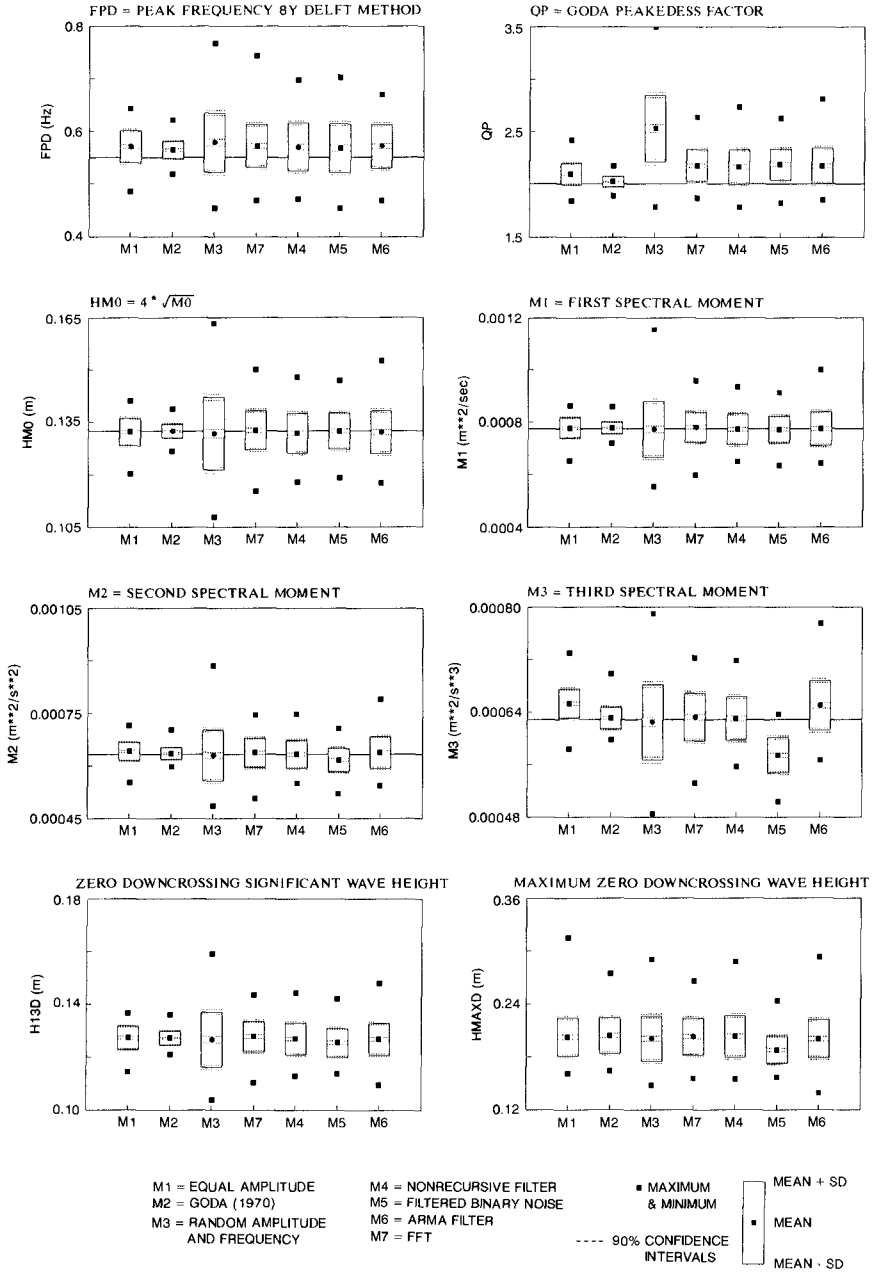

Fig.7a Wave Parameter Statistics for PM Spectrum

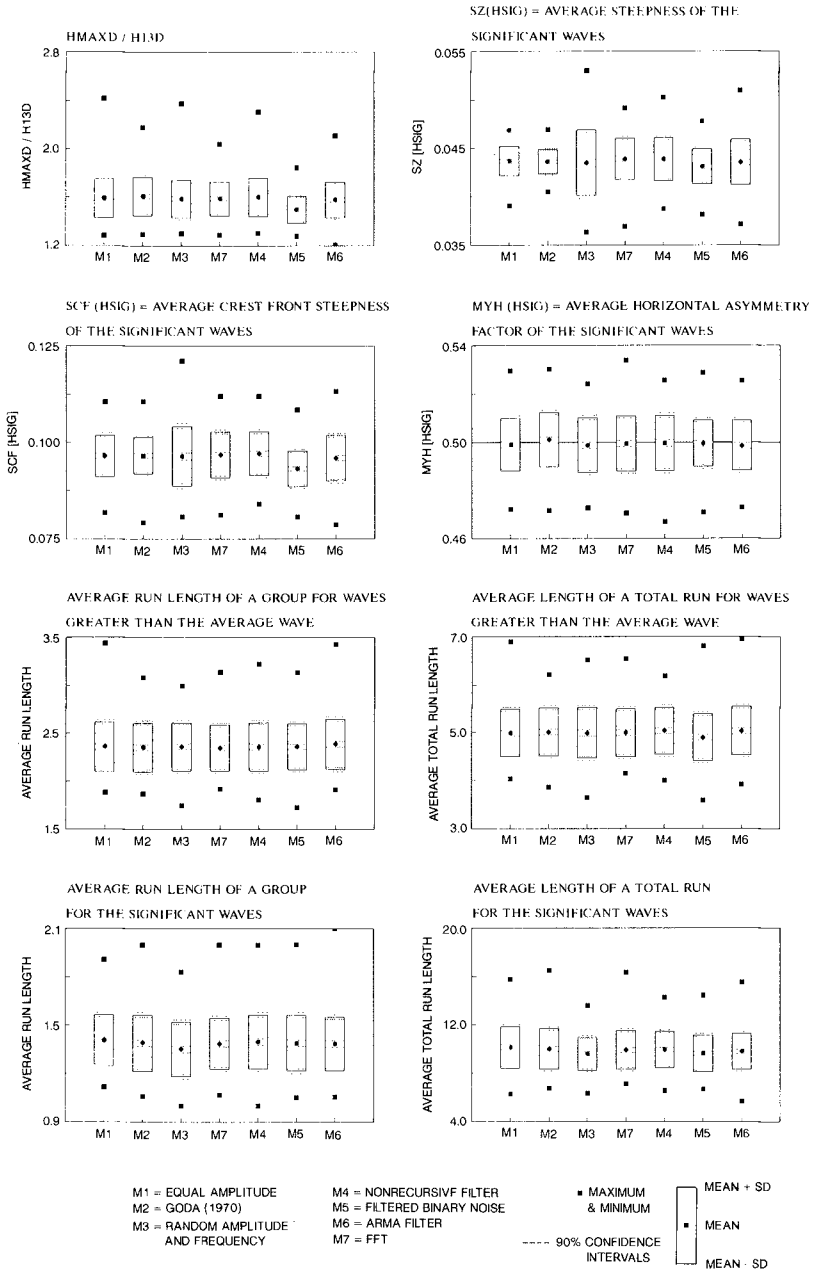

Fig.7b Wave Parameter Statistics for PM Spectrum

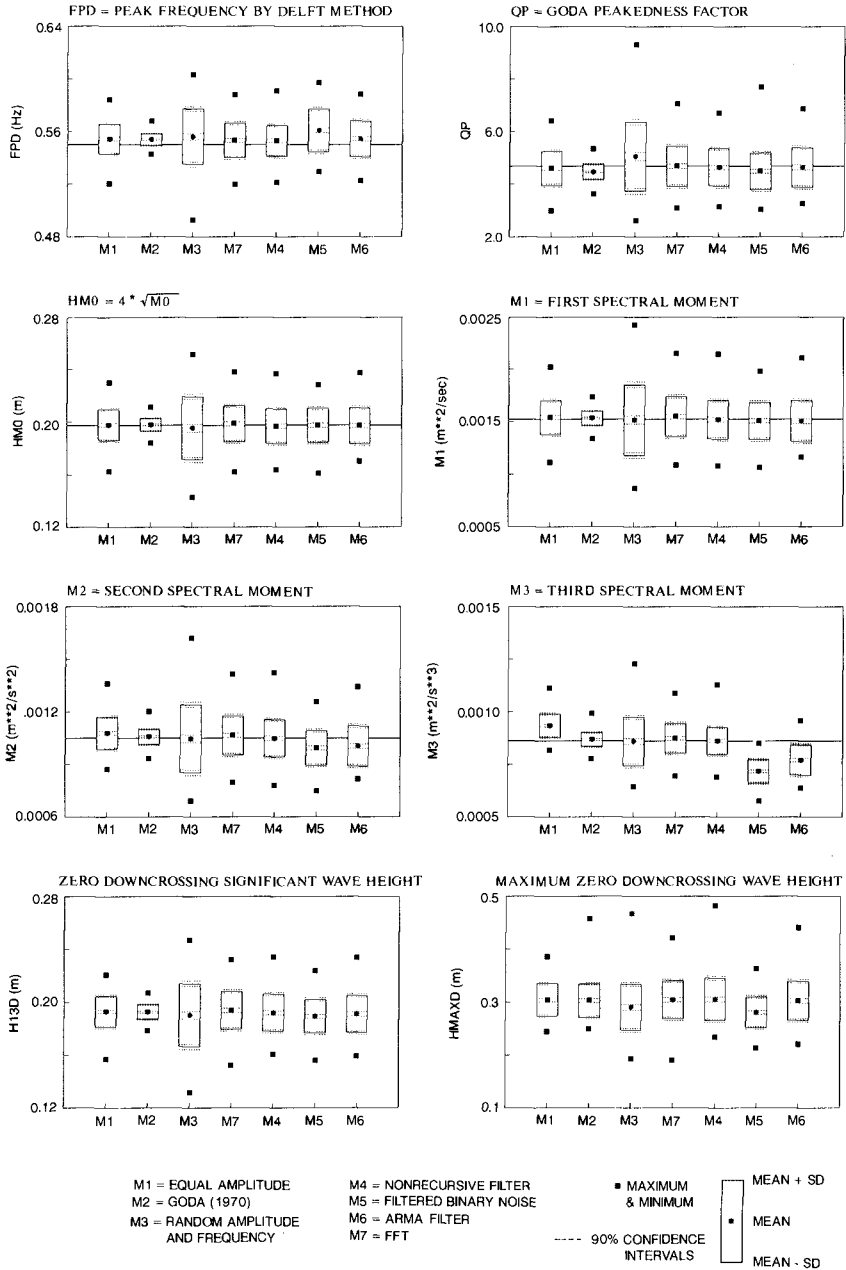

Fig.8a Wave Parameter Statistics for JONSWAP Spectrum

Fig.8b Wave Parameter Statistics for JONSWAP Spectrum

insufficient number of frequencies. A second set of wave records was therefore generated by method M3 with the number of frequencies increased from 200 to 600. This resulted in standard deviations which were similar to the other synthesis methods. For example, the mean value of QP was reduced from 2.53 to 2.24 and the standard deviation was reduced from 0.320 to 0.226 for the PM spectrum case.

Comparing the results of methods M4 and M7 in particular, it can be seen that there is very good agreement in both mean values and standard deviations for all wave parameters tested. The differences are generally small and well within the 90% confidence intervals in most cases. Although the standard deviation of HMAXD for method M7 is slightly smaller than that for method M4, the difference is probably not large enough to be significant. It must also be noted that the confidence intervals shown may not be very accurate since HMAXD is non-Gaussian.

Fig.9 Long Wave Parameter Statistics for JONSWAP spectrum

The results of the statistical analysis of the 4 long wave parameters are shown in Figure 9. Methods M1 and M2 have smaller variability than the others for both the standard deviation and the maximum elevation of the group bounded long wave component. Method M3 has larger variability than the

other methods for these parameters. In all cases, however, there is very good agreement between methods M7 and M4 for the mean values and standard deviations of the long wave parameters.

FFT APPROXIMATIONS OF NONHARMONIC WAVE RECORDS

A separate part of this study was to determine how well an FFT synthesized wave record could approximate typical wave records generated by the nonharmonic methods. It is well known that any continuous waveform of finite duration can be represented exactly by a Fourier series expansion. This result has limited practical value, however, since an infinite number of components with infinite bandwidth are required. Furthermore, Fourier representations are always cyclic whereas nonharmonic wave records are not. Consequently, Fourier representations of such records must generally cope with an implicit discontinuity. A further constraint imposed by most FFT algorithms is that the number of points in the Fourier time series must be an integer power of 2.

In order to deal with these problems, an iterative procedure was developed which can generate a very accurate FFT approximation to any arbitrary discrete time series of M points. The FFT approximation has N points where N is an integer power of 2 which is less than $2M$. The original M -point time series is first resampled at N points by simple linear interpolation. An initial set of Fourier coefficients is obtained by an FFT transform. These coefficients are then multiplied by Lanczos smoothing factors in order to minimize any Gibbs phenomenon oscillations associated with the implicit discontinuity in the original record. The initial FFT approximation is then obtained by an inverse FFT.

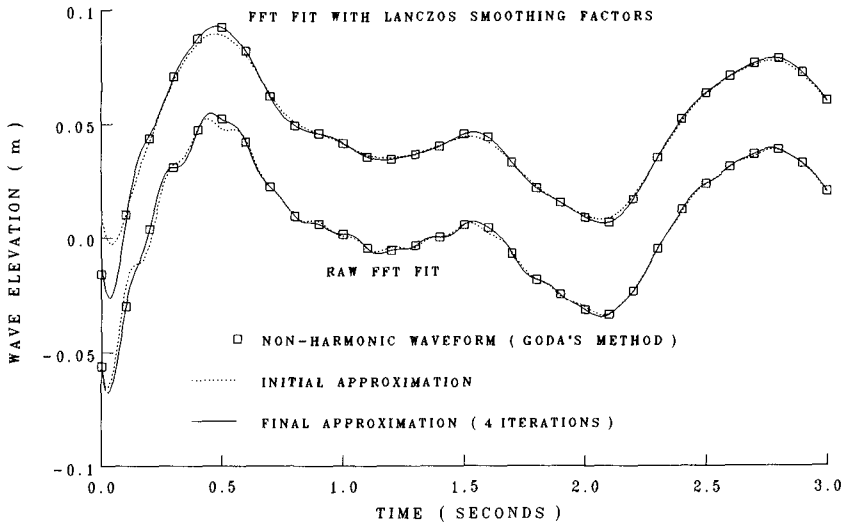

Fig. 10 FFT Approximations to a Method M2 Record

The initial FFT approximation is then resampled back to the original M time points by linear interpolation and subtracted from the original record to obtain a residual M -point record. The entire process is then applied to the residual record and repeated for 3 or 4 iterations until the amplitude of the residual record becomes sufficiently small.

An example of this procedure is shown in Figure 10 for the case of a nonharmonic wave record synthesized by method M2 (Goda's method). The lower pair of curves shows the result obtained without including the Lanczos smoothing factors. The Gibbs oscillations are quite evident. It can be seen from the upper pair of curves that the Lanczos factors do an excellent job of suppressing these oscillations and the final FFT representation is a very good approximation of the original nonharmonic wave record. The only noticeable difference is a small negative peak at the beginning caused by the cyclic property of the FFT. Such effects are very localized, however, and a very close fit is obtained over the main part of the record. It should also be noted that this example was selected with a large discontinuity to emphasize this aspect whereas records are normally selected on zero crossing boundaries to minimize these effects. Three more FFT approximations of nonharmonic wave records are plotted in Figure 11. These results clearly demonstrate that the use of an FFT synthesis technique does not impose any significant constraints on the types of waveforms which can be represented.

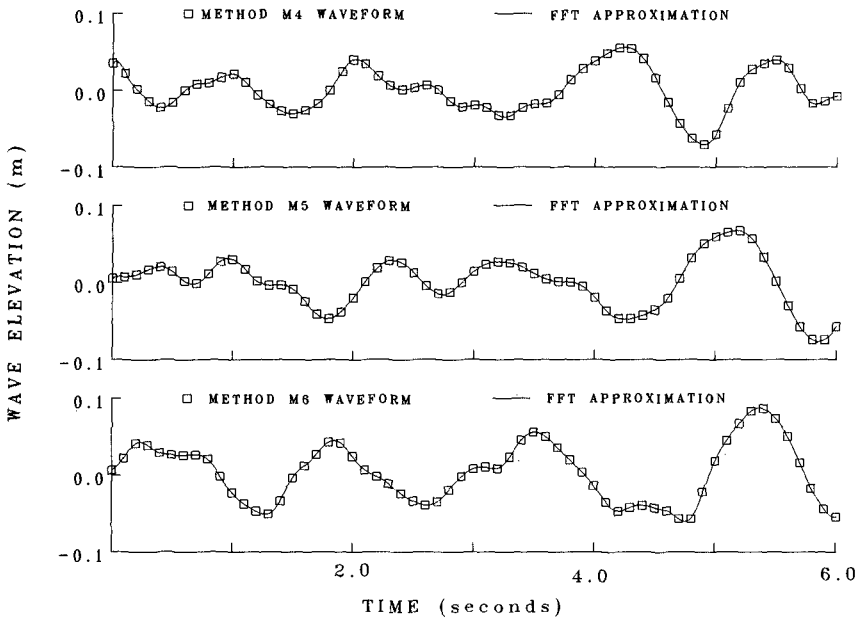

Fig.11 FFT Representation of 3 Nonharmonic Records.

DISCUSSION AND CONCLUSIONS

Methods M4 - M7 all produced very similar standard deviations for the wave parameters tested. As expected, methods M1 and M2 produced smaller standard deviations for the spectral parameters since they are spectrally deterministic in contrast to the other methods. Method M3 generally gave larger wave parameter variability than the other methods when 200 frequencies were used but the variability was similar to the other methods when the number of frequencies was increased to 600.

The nonrecursive filtered white noise method M4 should produce the most realistic wave records because it imposes no constraints on the basic assumption of a stationary Gaussian process and it provides a closer spectral fit than the ARMA filter method. There are no significant differences in either the mean values or the standard deviations of the wave parameters produced by the FFT method M7 and those produced by method M4. It is therefore concluded that the use of FFT synthesis methods does produce realistic Gaussian wave records provided that the maximum number of frequencies is used for the required record length. In other words, the FFT wave records will be realistic if $\Delta f = 1/(\text{record length})$ so that the wave records are never actually recycled.

The nonharmonic superposition methods can generate very long non-repetitive wave records with a relatively small number of frequencies compared to FFT techniques. However, the results from method M3 demonstrate that the use of nonharmonic frequencies cannot compensate for a lack of frequency density. The number of nonharmonic frequencies over the main spectral band must be at least as large as those in an FFT representation in order to obtain correct short-term variability of certain wave parameters.

It has been shown that any discrete time domain wave record generated by a nonharmonic synthesis method can be approximated by an equivalent FFT time series with no significant residual error. Thus, the use of an FFT representation per se does not impose any practical limitations on the types of waveforms which can be produced. It is sometimes claimed that filtered noise methods are superior to FFT techniques because they have continuous rather than discrete spectra. An FFT approximation to a filtered white noise record will have Gaussian Fourier coefficients so this is simply an alternate implementation of the RFC method. Since the time domain wave records are virtually identical, a finite length record generated by a filtered noise method cannot be considered to have a more continuous spectrum than a record of the same length generated by the RFC FFT technique.

In summary, all of the synthesis methods investigated can be used in principle to generate realistic Gaussian wave records but spectrally nondeterministic procedures are necessary for correct short term variability. The choice of a method is thus largely a matter of computational efficiency and convenience. The ARMA filter and FFT methods were found to be 20 to 30 times faster than the nonharmonic superposition methods. The ARMA filter technique is slightly faster than the FFT but the design of ARMA filters is

somewhat difficult and time consuming. In most applications, the convenience of FFT techniques will usually outweigh the marginal speed benefit of the ARMA filter approach.

CHAPTER 7

ON THE TRANSFORMATION OF WAVE STATISTICS DUE TO SHOALING

E.P.D. Mansard¹, E.R. Funke¹, J.S. Readshaw² & R.K. Girard¹

ABSTRACT

The results of a 1:40 scale physical model investigation into the shoaling process are described. The model simulated a nearly constant slope of 1:40 with wave measurements made at a depth of approximately 25 and 9 m. Two hundred individual tests were undertaken, with four offshore significant wave heights as the only test variant. The results indicate that the most severe nearshore wave conditions do not occur with the worst offshore conditions. There is evidence of a significant increase in low frequency wave energy in the nearshore zone.

INTRODUCTION

For the laboratory design of coastal structures in depth-limited situations, it is customary to simulate a pre-specified sea state in the offshore region of a model and let the shoaling take its natural course on a bathymetry similar to that found in nature. The final design of the structure is then related to that offshore sea state and its probability of occurrence. Coastal engineers usually design their structures to withstand 1 in 100 year storm conditions.

The transformation of wave statistics due to shoaling has been an active field of research for a number of years. However, the complex physics of this phenomenon is not thoroughly understood. An extensive series of model investigations were carried out recently, for the purpose of gaining a better understanding of this phenomenon. This study included only one bathymetry and only one offshore water depth. Only one spectral shape with only one peak frequency was used. Waves were only recorded at two locations. In this sense, the investigation was simply a case study.

This research was motivated by the discovery of certain unexplained inconsistencies during a commercial model study. It was therefore undertaken to obtain a better insight into

¹ Hydraulics Laboratory, National Research Council
Ottawa, Ont., Canada, K1A 0R6

² W.F. Baird Associates Ltd., 38 Antares Drive,
Ottawa, Ont, Canada, K2E 7V2

the shoaling phenomenon and to quantify the wave parameter statistics that may result from shoaling. Some of the results have previously been reported by Readshaw et al (1987). Further results are presented here. Therefore, this paper complements the information contained in Readshaw et al (1987) and is intended to provide the basis for further comprehensive research.

The model investigation has shown that, for a given offshore sea state described solely by the variance spectral density, the severity of the nearshore wave climate can be grossly misjudged. Although this research has led to several useful conclusions, which are stated below, it must be expected that other test conditions for wave period, water depth, bathymetry and perhaps wave direction may lead to different results than those reported here. Nevertheless, it is believed that the conditions for this investigation are typical and the results will give a general indication of what may be expected for other situations.

EXPERIMENTAL SET-UP AND TEST WAVE CONDITIONS

Figure 1 shows a sketch of the experimental set-up. Waves were allowed to shoal from a depth of approximately 25.2 m (full scale units) to a depth of 8.6 m, where a breakwater was to be constructed. For convenience, the deeper region will be referred to here as the offshore zone and the other as the nearshore zone. The bathymetry that was used in this study had a nearly constant slope of approximately 1:40. This corresponded to the conditions in nature after which the study was modelled. The scale factor of the model was 1:40.

Waves were generated from numerically synthesized data derived from a JONSWAP spectral density with a peak period of 16.6 s and a γ value of 3.3. The method of wave synthesis was the "Random Complex Spectrum" method³ described by Funke & Mansard (1984). This method of synthesis creates wave trains from a Gaussian distributed white noise complex spectrum which is filtered by the specified target spectrum. It is known that it produces wave trains which mimic the variability of the natural sea state. Fifty different time series of 20 minute duration (full scale) were synthesized from a common JONSWAP target spectrum. Each of these was rescaled in four different ways, creating therefore four different sets of wave generator command signals, one for each offshore significant wave height of 4.8 m, 6.3 m, 7.8 m and 9.3 m. The rescaling was adjusted for each individual wave record to ensure that the desired variance was achieved near the wave board. As a result, 200 command signals were synthesized originating from a common spectral shape with common peak frequency, but differing only in their variance. Each set contained therefore 50 time series which were identical to those in the other sets in every respect except the amplitude scale. This is an important point, because the only parameter which was varied for the purpose of this study was the offshore significant wave height H_{m0} .

³ Miles and Funke (1988) refer to this method as the "Random Fourier Coefficient" method. A description of its statistical characteristics is also provided in their publication.

ANALYSIS OF WAVE DATA

All wave data was subjected to spectral density and zero-crossing analysis. From the spectral density the following parameters were obtained:

- f_{pD} - the peak frequency according to the Delft method (IAHR List of Sea State Parameters, 1986). It was computed as the centroid of the part of the spectrum which is delimited by its first and its last crossing of a threshold that is 80% of the spectral peak value.
- H_{m0} - the estimate of the significant wave height which was computed as $4 \cdot \sqrt{m_0}$, where m_0 was obtained by integration of the spectral density from $0 < f < 0.5$ Hz. This corresponded, in this case, to an upper limit of $8.5f_p$ and was for all practical purposes an upper limit of infinity. For reasons to be explained later, this parameter was also evaluated for the integration limits of $0.03 < f < 0.5$ and $0.03 < f < 0.15$ Hz.
- $m_{0,LW}$ - the variance of the long waves which was computed by numerical integration of the spectral density from $0 < f < 0.03$ Hz. This corresponded, in this case, to an upper limit of $0.5f_p$.

From zero crossing analysis the following parameters were obtained:

- $H_{1/3}$ - the significant wave height, computed as the average of the highest one-third of all zero down and zero up-crossing waves.
- $H_{1/10}$ - the average one-tenth of all wave heights from zero down and zero up-crossing analysis.
- $H_{1/20}$ - the average one-twentieth of all wave heights from zero down and zero up-crossing analysis.
- H_{max} - the larger of the maximum zero up- or down-crossing wave.
- $\bar{S}_{H1/3,d}$ the average steepness of the significant waves. This is the average of the ratios of wave heights and wave lengths for those waves which belong to the highest one-third of all zero down-crossing waves.

RESULTS AND DISCUSSION

The results presented here correspond to waves measured at the two locations shown in the Figure 1. Four pairs of example wave records, as measured by the two probes, are shown in Figure 2. It will be noticed that the offshore wave record is given below the corresponding nearshore wave record for each of the four significant wave heights given in this example. Closer comparison between the four offshore wave records will reveal that they originate from the same time history which was scaled to yield the desired wave heights $H_{m0} = 4.8, 6.3, 7.8$ and 9.3 m. Evidently, for the higher wave heights, the offshore wave crests become more accentuated and some distortions occur because of breaking. Nevertheless, except for scaling, the inputs to the four tests were the

FIGURE 1
DEFINITION SKETCH OF THE EXPERIMENTAL SET-UP

same and hence this figure illustrates the influence of just the variance of the offshore wave activity on the transformation of wave profiles from deep to shallow water.

The nearshore wave records in Figure 2 were synchronized to the offshore wave trains. The arrows in the wave records point approximately to corresponding points in the two recordings, making allowance for the propagation delay. From observations during the tests, it was apparent that the wave trains on the left hand side of the figure describe the shoaling situation before breaking in the nearshore zone, whereas the right hand wave records illustrate the nearshore post-breaking state.

Figure 2 shows, as one would expect, that the nearshore wave profiles have sharper crests and flatter troughs when compared to the nearly sinusoidal profiles in deep water. Even for the lowest significant wave height, it is difficult to identify a similarity between the nearshore and the corresponding offshore wave record. However, with some stretch of the imagination, one can see a correspondence between wave groups. But, for the largest significant wave height, all meaningful relationship seems to have vanished. It can be speculated that, as the variance of the offshore sea state increases, the individual nearshore wave profiles steepen up much more quickly during shoaling and become unstable. This results then in the breaking of waves and their subsequent reconstitution before they reach the hypothetical breakwater site.

Another interesting observation is the skewness of waves in the nearshore zone. This is more pronounced for large offshore wave heights. It is speculated that this is the result

FIGURE 2
 SAMPLE TIME SERIES MEASURED BY THE TWO PROBES
 FOR THE FOUR SIGNIFICANT WAVE HEIGHTS (H_{m0})
 OF THE TARGET SPECTRUM

of an interaction between the shoaling waves and the return currents from the beach.

The spectral densities of the eight wave trains in Figure 2 are shown in Figure 3 with each corresponding pair of spectra for a nearshore and an offshore case superimposed on the same graph. From this it can be seen that, in spite of a substantial increase in the variance of the offshore sea state, there is not an equivalent increase in the variance in the nearshore sea state, evidently because of energy loss due to breaking. On the other hand, as a result of shoaling, the nearshore spectra indicate a significant increase in the variance for the low frequency range (i.e. $0 < f < 0.03\text{Hz}$). It can also be noted, that the peak frequencies of the nearshore spectra tend to be lower than those of the offshore spectra. This frequency shift can be partly attributed to possible transfer of energy from high to low frequencies during the

FIGURE 3
 SPECTRAL TRANSFORMATION ON A 1:40 SLOPE
 FOR THE FOUR SIGNIFICANT WAVE HEIGHTS (H_{m0})
 OF THE TARGET SPECTRUM

breaking process. In general, the nearshore spectra are much broader than their offshore origins.

Figure 4 shows the results of the analysis for the offshore significant wave height of 9.8 m. The time series given in this figure, are the various wave parameters from the fifty offshore and nearshore wave records placed in sequential order.

It can be seen from this figure, that there is no significant correlation between offshore and nearshore wave parameters. Except for the peak frequency and the long wave energy, the variability of wave parameters is approximately the same. It is also evident that there is generally a significant increase in long wave energy as a result of

FIGURE 4
 SELECTED WAVE PARAMETERS , OFFSHORE AND NEARSHORE ,
 FOR 50 DIFFERENT REALIZATIONS OF THE TIME SERIES

shoaling. Although the command signals to the wave machine were rescaled to eliminate the variability of the offshore significant wave height, it is apparent that at the probe location 11 m from the wave board some variability has re-established itself. This is partly due to breaking and non-linear effects.

NON-LINEARITIES

The Laplace equation with proper boundary conditions is most often used for describing waves. Solutions of this equation can be obtained by the perturbation technique and waves are therefore of infinite order. However, for most practical applications, the first order solution to this equation is found to be quite satisfactory. But in shallow water, where the boundary conditions are principally non-linear, this equation would have to be solved to a higher order and, during this, two important phenomena will appear. These are the bounded sub- and the super-harmonics (Mansard et al 1988). The wave components resulting from these non-linearities travel with velocities bound to their fundamentals, while other components satisfy the linear dispersion relation. Barthel et al(1983) and Sand & Mansard(1986) show that classical first order wave generation theory does not properly satisfy the boundary conditions needed for the correct reproduction of these waves and therefore some spurious components of similar frequencies will appear in the simulations. This theory can be used to estimate the frequencies and their amplitudes as a consequence of shallow water boundary conditions, and permits therefore the prediction of spectral distortions.

Figure 5 shows two arbitrarily selected sample spectra measured by the first probe when using the target spectrum with a significant wave height $H_{m0} = 7.8$ m. On the left hand side of this figure, a comparison is shown between the expected spectral density for this particular realization and the one which was actually measured. The expected spectral density corresponds here to the one synthesized by the random complex spectrum, which is of course based on linear superposition of frequency components. It can be seen from this figure, that the measured energy content in the two frequency ranges of $0 < f < 0.03$ Hz and $0.1 < f < 0.5$ Hz are distinctly higher than expected. However, by applying second order wave and wave generation theory to the prediction of the wave spectra at this site, the agreement with the measured spectra is much improved as is shown on the right side of Figure 5.

RELATIONSHIP BETWEEN OFFSHORE AND NEARSHORE WAVE PARAMETERS

Examples of the relationship between offshore and nearshore wave heights are illustrated in Figures 6 and 7 for the four different offshore wave height parameters. In these illustrations a nearshore wave height parameter is plotted against the same offshore parameter.

In order to reduce the variability of wave height estimates as computed from 20 minute long records, the data were also analyzed by joining them first into blocks of 3 and 6 to give 1 and 2 hour averages of wave parameters. Figures 6 and 7 provide therefore the results for each of four different wave height parameters, calculated for three different averages.

FIGURE 5
NON-LINEAR PREDICTION OF WAVE SPECTRA

$H_{m0}=7.8\text{m}$ $T_p=16.6\text{s}$ $h=25.2\text{m}$

DISTANCE FROM PADDLE = 11m

As one would expect, it can be seen from these results that the variability does decrease with increasing record lengths. The 2 hour averages illustrate quite clearly the general trend in the shoaling process. It will be seen that the nearshore wave heights do not increase with increasing offshore wave height. There is also an indication that for three of these parameters there is a slight reverse trend in as much as the nearshore wave height seems to decrease for very large offshore wave heights.

Figure 8 presents the data in a different mode. Following a statistical analysis of nearshore wave height parameters obtained from 20 min records, the extrema, the average as well as the average +1 and -1 standard deviation were plotted against the offshore significant wave height H_{m0} . This was also done for the variance of the long waves and the steepness of the significant waves.

RELATIONSHIP BETWEEN FREQUENCY AND TIME DOMAIN ESTIMATION OF SIGNIFICANT WAVE HEIGHT

In deep water, the significant wave heights derived either by zero crossing analysis or by spectral density analysis are

FIGURE 6
VARIABILITY OF SIGNIFICANT WAVE HEIGHTS

FIGURE 7
 VARIABILITY OF $H_{1/10}$ AND $H_{1/20}$

proportional to each other. This is because deep water waves are, for all practical purposes, Gaussian in character. However, in the nearshore zone, this assumption is not valid and the estimation formula for the significant wave height, $H_{1/3} \approx 4 \cdot \sqrt{m_0}$ no longer applies. There is also a real difficulty in deciding over what band of frequencies the spectral moment m_0 should be evaluated, because the nearshore spectrum contains significant energy below and above the original first order spectrum.

The left side of Figure 9 gives the average over 50 wave records of the ratio between the two nearshore significant wave heights, one as computed from zero crossing and the other as estimated from spectral analysis. For the latter, the variance of the nearshore sea state was computed with three different bandwidths, i.e.:

- $0 < f < 0.5$ Hz, which for all practical purposes, covers the range from 0 to ∞ ,
- $0.03 < f < 0.5$ Hz, which excludes the long wave frequency range, and
- $0.03 < f < 0.15$ Hz, which represents the typical first order frequencies contained between $0.5f_p < f < 2.5f_p$.

The reasons for choosing these integration limits are as follows. Waverider buoys cannot give outputs for wave periods longer than 30 seconds. Therefore, wave data recorded by them do not contain meaningful energy in the low frequency band. Furthermore, because of communication interference, it is generally presumed that spectral energy beyond $f > 2.5f_p$ must be considered background noise. By applying the same limits to this data collected in the laboratory, which are usually imposed implicitly or explicitly on natural wave data, Figure 9 may serve a useful purpose in the interpretation of some wave spectra recorded in nature.

The right hand side of Figure 9 gives the shoaling coefficient as a function of the offshore wave height. This coefficient is computed as the ratio of the average nearshore to the average offshore wave height. Once again, various estimates of the significant wave height are displayed. In case of the significant wave height estimated from spectral integration, this is done with the three different cut-off frequencies.

CONCLUSIONS AND RECOMMENDATIONS

For the conditions which prevailed during the test series, the study concluded that:

- The significant wave height in the nearshore zone derived from zero-crossing analysis is generally larger than the nearshore significant wave height estimated from the zeroth spectral moment function (see also Thompson & Vincent 1985). This is apparent from Figure 9.
- A particular nearshore wave height can be realized by a wide range of offshore sea states. This information is contained in Figure 8.
- It is possible for the nearshore zero-crossing significant wave height to be larger than the offshore significant wave

height. This is the case here for the group of offshore wave heights of 4.8 m, as shown in Figure 9.

- On the average, it may be predicted that the worst nearshore wave conditions may not be produced by the worst offshore sea states. The offshore wave conditions of moderate wave height may lead to the worst nearshore significant wave heights. In this case the worst conditions arise probably at an offshore wave height of 7.8 m (c.f. Figures 6 and 7).
- As a result of the shoaling process, there is a significant increase of long wave energy in the nearshore zone. Figures 3 and 8 attest to this.
- The nearshore spectra tend to have a larger peak period than the corresponding offshore spectra. Otherwise, there is no simple relationship between offshore and nearshore peak periods. This is indicated in Figure 3.

The results presented so far illustrate the fact that for a given offshore sea state a large combination of nearshore sea states, some severe and some less severe, can be obtained. This is a consequence of statistical variability, and it implies that in every model study of depth limited situations one cannot be absolutely sure that the worst nearshore wave conditions have been simulated for a specified offshore sea state. One obvious solution to this problem is to simulate very long wave records in physical model studies. However, this may become expensive and time consuming since design optimization of a given structure usually requires many repetitions of the same test conditions in order to optimize several design parameters.

To overcome this difficulty, the technique currently used at the Hydraulics Laboratory of the NRCC, consists of first determining experimentally the worst nearshore wave climate by testing a large number of time domain realizations for each offshore sea state. This can be done by building a structure, say a preliminary design of a breakwater, at the projected site and then by identifying which of the time domain realizations results in the maximum number of breaking waves impacting on the structure. If this approach is not practical, the various nearshore wave records obtained during the preliminary tests can be subjected to frequency and time domain analyses. For example, at the NRCC Hydraulics Laboratory the following nearshore wave parameters are computed:

- the estimate of the significant wave height, H_{m0} ,
- the variance of long waves, $m_{0,LW}$,
- the zero crossing significant wave height, $H_{1/3}$,
- the average of the highest 1/10th zero crossing waves, $H_{1/10}$,
- the average crest front steepness of the significant waves, $\bar{S}_{H1/3}$, and
- the Groupiness factor value, GF.

Those offshore time series which give consistently the worst nearshore wave conditions for most of these six parameters are then selected as being the most suitable for the design study.

None of the above techniques are entirely satisfactory because the decisions made during this approach are very

subjective and are often based on intuition. It is speculated that there is no single wave parameter, but rather a combination of several parameters which may form a relevant criterion in the selection process. Furthermore, every structure is different and may therefore require different criteria for testing.

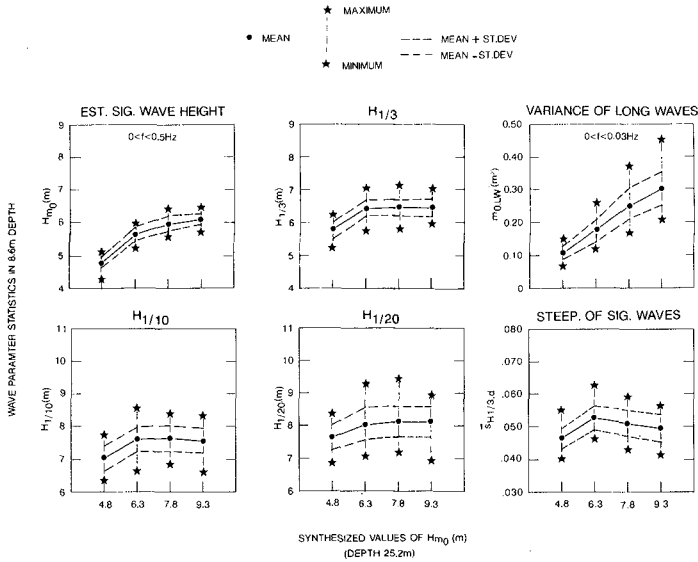

FIGURE 8
EFFECT OF OFFSHORE WAVE HEIGHTS ON NEARSHORE WAVE STATISTICS

FIGURE 9
EFFECT OF OFFSHORE WAVE HEIGHTS ON THE RATIO OF NEARSHORE $H_{1/3}/H_{m0}$ AND ON THE SHOALING COEFFICIENT

Evidently, the best approach is to strive towards a better understanding of the relevance of various wave parameters, such as grouping, crest front steepness etc., to the stability of a structure and to establish their relationship to the offshore sea state through a better understanding of the shoaling mechanism. However, because of the complexity of the problem, a major research effort with international cooperation will undoubtedly be required.

Last, but not least, it should be apparent from information contained in Figure 8, that the distribution functions for the probability of occurrence of offshore wave parameters require a transformation in order to estimate from them the return period of a nearshore design wave. It can be seen, for example, that a nearshore significant wave height of, say, 6.5 m can be produced by all offshore sea states with significant wave heights equal to or greater than 6.3 m. This fact alone places a new perspective on the design of coastal structures.

CHAPTER 8

WAVE FIELD BEHIND THE PERMEABLE DETACHED BREAKWATER

Shan-Hwei Ou¹ Shiaw-Yih Tzang² and Tai-Wen Hsu²

ABSTRACT

Based on the concept of linear superposition, the model for combined wave refraction and diffraction developed by Liu et al. is extended to the situation of permeable detached breakwaters in a slowly varying water depth. Two cases are investigated which include a semi-infinite permeable breakwater and a single permeable breakwater. Laboratory results with a particular transmission coefficient in a wave basin are used to compare with the theoretical results. Fair agreements are found.

1. INTRODUCTION

The use of detached breakwaters as a countermeasure against beach erosion is ever increasing in the past. In practice, most of the breakwaters are constructed with the armor units so that waves can transmit through the breakwaters. The wave field behind permeable detached breakwaters has not yet been fully understood because of the complicated phenomena induced by the breakwater and the bottom topography.

Hotta (1978) proposed a wave superposition model around the permeable breakwaters due to the wave diffraction. The cases studied by Hotta are in a constant water depth with normal incident waves. Due to the fact that the water depth

1. Professor, Ph.D., Department of Hydraulics & Ocean Engineering, National Cheng Kung Univ., Tainan, Taiwan 70101, Rep. of China.

2. Graduate Student, ditto.

is changing in the field, the wave diffraction must be calculated under the consideration of wave refraction. The purpose of this study is to attempt to clarify the wave height distribution behind permeable detached breakwaters in a slowly varying water depth with obliquely incident water waves.

The applicability of linear superposition of combined refraction-diffraction wave field proposed by Liu, Lozano and Pantazaras (1979) has been verified by Ou and Tzang (1986) for impermeable detached breakwaters. This paper uses the same approach for the study of wave height distribution behind permeable breakwaters. Numerical examples are given and a series of experiments are conducted in a wave basin to compare the results.

2. REFRACTION-DIFFRACTION EQUATIONS

The wave patterns near a detached breakwater have been studied in the past decade by the combined effects of refraction due to slowly varying water depth and diffraction by the breakwater. Much progress have been achieved in both extending the applicability of the theoretical framework and saving the computer time and storage in numerical scheme (Liu and Mei, 1976; Liu et al. 1979; Tsay and Liu, 1982; Isobe, 1986). In this section we briefly summarize the combined refraction-diffraction equations developed by Liu et al. (1979) and Liu (1982) for the impermeable detached breakwater. These equations will be used in the following section for the derivation of wave superposition behind permeable detached breakwater.

Fig. 1 Definition sketch and coordinate system

Considering small amplitude incident waves with the incident wave amplitude a_0 , and the radian frequency ω and the angle of incidence θ_0 as shown in the coordinate system of Fig. 1, the leading order asymptotic solutions for the free surface displacement η and the velocity potential ϕ can be expressed as follows:

$$\eta(x, y, t) = \gamma' A(x) [G(\mathbb{H})e^{iS} + G(\bar{\mathbb{H}})e^{i\bar{S}}] e^{-i\omega t} \dots\dots\dots(1)$$

$$\phi(x, y, t) = - \frac{ig \eta(x, y, t)}{\omega} \frac{\cosh k(z+h)}{\cosh kh} \dots\dots\dots(2)$$

where

$$\begin{aligned} \gamma' &= \pi^{-1/2} \exp(-i\pi/4) \\ G(\zeta) &= \int_{-\infty}^{\zeta} e^{i\sigma^2} d\sigma \dots\dots\dots(3) \end{aligned}$$

and $A(x)$ represents the shoaling and refraction factor as expressed by Nielsen (1982) in explicit form as

$$\begin{aligned} A(x) &= a_0 \sqrt{\cos \theta_0} \left[1 - \frac{2\pi h}{L_0} \left(1 - \frac{h}{L_0} \right)^2 \sin^2 \theta_0 \right]^{-0.25} \left(\frac{8\pi h}{L_0} \right)^{-0.25} \\ &\quad \exp\left(\frac{\pi h}{2L_0} \right) \dots\dots\dots(4) \end{aligned}$$

$G(\zeta)$ can be written in terms of the well known Fresnel integrals as

$$G(\zeta) = \left(\frac{\pi}{2} \right)^{1/2} \left\{ \left[\frac{1}{2} + C(\zeta^2) \right] + i \left[\frac{1}{2} + S(\zeta^2) \right] \right\} \dots\dots\dots(5)$$

where

$$\begin{aligned} C(\zeta^2) &= \frac{1}{\sqrt{2\pi}} \int_0^{\zeta^2} \frac{\cos \tau}{\tau^{1/2}} d\tau \\ S(\zeta^2) &= \frac{1}{\sqrt{2\pi}} \int_0^{\zeta^2} \frac{\sin \tau}{\tau^{1/2}} d\tau \dots\dots\dots(6) \end{aligned}$$

The arguments of the function $G(\zeta)$ in Eq. (1) are defined as

$$\mathbb{H}^2 = R - S, \quad \bar{\mathbb{H}}^2 = R - \bar{S} \dots\dots\dots(7)$$

where S, \bar{S}, R are the phase functions of the incident waves, the reflected waves and the radiated waves generated by an oscillatory point source at the tip of the breakwater, respectively. The value of \mathbb{H} is negative inside the shadow

region and is positive elsewhere. On the other hand, \bar{H} is positive in the reflection region and is negative elsewhere. The phase functions are expressed as follows:

$$S = - \int_0^x k \cos \theta \, dx + K_0 y \quad \dots\dots\dots(8)$$

$$\bar{S} = \int_0^x k \cos \theta \, dx + K_0 y \quad \dots\dots\dots(9)$$

$$R = - \int_0^x k \cos \theta \, dx + K_t y \quad \dots\dots\dots(10)$$

with

$$K_0 = k \sin \theta = k_0 \sin \theta_0 \quad \dots\dots\dots(11)$$

$$K_t = k \sin \theta = k_t \sin \theta_t \quad \dots\dots\dots(12)$$

where k_t and θ_t are the wave number and the initial angle of incidence of a radiated wave ray at the tip of the breakwater, respectively.

3. WAVE SUPERPOSITION

Based on the concepts of Hotta (1978), the wave height distributions behind permeable detached breakwater in a slowly varying water depth are established by extending the solutions developed by Liu et al. (1979). Substituting Eq. (5) into Eq. (1), the free surface displacement η can be expressed as follow:

$$\eta_D = \frac{A(x)}{\sqrt{2}} e^{-i(\frac{\pi}{4} + \omega t)} \{ [(\frac{1}{2} + c_1) + i(\frac{1}{2} + s_1)] e^{iS} + [(\frac{1}{2} + c_2) + i(\frac{1}{2} + s_2)] e^{i\bar{S}} \} \quad \dots\dots\dots(13)$$

where c_1, s_1 and c_2, s_2 are the Fresnel integrals for the incident waves and reflected waves, respectively. The subscript D refers to diffraction.

For brevity, the basic assumptions for this paper is the same as Ou and Tzang (1986). According to the definition of \bar{H} and \bar{H} , and from Eqs. (5) and (6), we define $G(\zeta)$ for clarity as follow:

$$G(-\zeta) = \left(\frac{\pi}{2}\right)^{1/2} \left\{ \left[\frac{1}{2} - C(\zeta^2) \right] + i \left[\frac{1}{2} - S(\zeta^2) \right] \right\} \dots\dots\dots(14)$$

A Semi-infinite Permeable Detached Breakwater

According to Hotta's (1978) concepts, the waves behind permeable breakwater consist of two main parts: diffracted

Fig. 2 Refraction-Diffraction function for a semi-infinite permeable breakwater

waves from impermeable breakwater and transmitted wave through permeable breakwater. As shown in Fig. 2, a permeable breakwater is placed parallel to the shoreline from y=0 to y=-∞. Waves in region A (incident region) and region B (diffraction region) are assumed to be the superposition of diffracted waves (Fig.2-(1)) and transmitted waves (Fig. 2-(2)). The free surface displacement in region A is

$$\eta = \gamma' A(x) [G(\bar{H}) e^{iS} + G(-\bar{H}) e^{i\bar{S}}] e^{-i\omega t} + \alpha \gamma' A(x) [G(-\bar{H}) e^{iS} + G(-\bar{H}) e^{i\bar{S}}] e^{-i\omega t} \dots\dots\dots(15)$$

where α is the transmission coefficient of permeable breakwater. From Eqs. (3), (5) and (14), we have

$$\eta = \frac{1}{\sqrt{2}} A(x) |D_{1A}(x, y)| e^{-i(\omega t + \pi/4)} \dots\dots\dots(16)$$

where $D_{1A}(x, y)$ is the refraction-diffraction function and subscript A refers to region A. Hence, $D_{1A}(x, y)$ in its final form is:

$$D_{1A}(x, y) = \left\{ \left[\frac{1+\alpha}{2} + (1-\alpha) C_1 \right] \cos S - \left[\frac{1+\alpha}{2} + (1-\alpha) \right. \right.$$

$$\begin{aligned}
 & S_1 \} \sin S + \left[\frac{1+\alpha}{2} - (1+\alpha)C_2 \right] \cos \bar{S} - \left[\frac{1+\alpha}{2} \right. \\
 & \left. - (1+\alpha)S_2 \right] \sin \bar{S} \} + i \left\{ \left[\frac{1+\alpha}{2} + (1-\alpha)C_1 \right] \right. \\
 & \left. \sin S + \left[\frac{1+\alpha}{2} + (1-\alpha)S_1 \right] \cos S + \left[\frac{1+\alpha}{2} - \right. \right. \\
 & \left. \left. (1+\alpha)C_2 \right] \sin \bar{S} + \left[\frac{1+\alpha}{2} - (1+\alpha)S_2 \right] \cos \bar{S} \right\} \dots (17)
 \end{aligned}$$

Similarly, we can derive $D_1(x,y)$ in region B in the same manner (see Tzang (1986) for details). Taking α equal to zero, the final equations agree with the solutions for a impermeable breakwater.

A Single Permeable Detached Breakwater

For a single impermeable detached breakwater, Ou and Tzang (1986) has developed a solution for the wave height distribution. When the breakwater is permeable, the waves behind the breakwater are assumed to be the superposition of the waves arising from an impermeable breakwater and the waves multiplied by α passing through a gap as described by Ou and Tzang (1986), as shown in Fig. 3. The free surface displacement based on the above assumption is as

$$\eta = \eta_s + \alpha \eta_g \dots \dots \dots (18)$$

The subscript s denotes a single impermeable detached breakwater, g denotes a single gap in a long breakwater.

Now we should consider the coordinate system first. The origin of the coordinate is located at the center of the breakwater. As described in the last section, we have

$$\begin{aligned}
 D_{2A}(x,y) = & \left\{ \left[\frac{1+\alpha}{2} + (1-\alpha)C_{1r} \right] \cos \left(S_r - \frac{\pi}{4} \right) \right. \\
 & - \left[\frac{1+\alpha}{2} + (1-\alpha)S_{1r} \right] \sin \left(S_r - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} \right. \\
 & \left. - (1+\alpha)C_{2r} \right] \cos \left(\bar{S}_r - \frac{\pi}{4} \right) - \left[\frac{1+\alpha}{2} - (1+\alpha)S_{2r} \right] \\
 & \left. \sin \left(\bar{S}_r - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} - (1-\alpha)C_{1t} \right] \cos \left(S_t - \frac{\pi}{4} \right) \right\}
 \end{aligned}$$

$$\begin{aligned}
 & - \left[\frac{1+\alpha}{2} - (1-\alpha) S_{1i} \right] \sin \left(\bar{S}_i - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} \right. \\
 & \left. - (1+\alpha) C_{2i} \right] \cos \left(\bar{S}_i - \frac{\pi}{4} \right) - \left[\frac{1+\alpha}{2} - (1+\alpha) S_{2i} \right] \\
 & \sin \left(\bar{S}_i - \frac{\pi}{4} \right) - \alpha \sqrt{2} \cos S_0 \} + i \left\{ \left[\frac{1+\alpha}{2} + (1-\alpha) C_{1r} \right] \right. \\
 & \left. \sin \left(S_r - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} + (1-\alpha) S_{1r} \right] \cos \left(S_r - \frac{\pi}{4} \right) \right. \\
 & \left. + \left[\frac{1+\alpha}{2} - (1+\alpha) C_{2r} \right] \sin \left(\bar{S}_r - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} \right. \right. \\
 & \left. \left. - (1+\alpha) S_{2r} \right] \cos \left(\bar{S}_r - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} - (1-\alpha) \right. \right. \\
 & \left. \left. C_{1i} \right] \sin \left(S_i - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} - (1-\alpha) S_{1i} \right] \right. \\
 & \left. \cos \left(S_i - \frac{\pi}{4} \right) + \left[\frac{1+\alpha}{2} - (1+\alpha) C_{2i} \right] \sin \left(\bar{S}_i - \frac{\pi}{4} \right) \right. \\
 & \left. + \left[\frac{1+\alpha}{2} - (1+\alpha) S_{2i} \right] \cos \left(\bar{S}_i - \frac{\pi}{4} \right) - \alpha \sqrt{2} \sin S_0 \right\} \dots (19)
 \end{aligned}$$

Fig. 3 Refraction-Diffraction function for a single detached permeable breakwater

where the subscripts r and ℓ denote the effects of the tip located on the right hand side and left hand side of the origin, respectively. Subscript o denotes the case without the appearance of the breakwater. Similarly, we can also derive $D_2(x,y)$ in region B (diffraction region) and in region

C (incident region) in a similar manner (see Tzang (1986) for details). Taking α equal to zero, the final equations also agree with the solutions developed by Ou and Tzang(1986) for a single impermeable detached breakwater.

4. NUMERICAL RESULTS

In this section simple numerical results are given. Computations for different values of transmission coefficient are given.

Fig. 4 Definition sketch for the detached breakwater

As shown in Fig. 4, the geometry chosen is as follows. The beach has a uniform slope $1/50$ in the x direction. The water depth of the location of breakwater is fixed at $h_R=7m$. The semi-infinite permeable breakwater is placed from $y=0$ to $y=-\infty$. The length of the single permeable detached breakwater is $L_B=700m$; the wave period $T=10$ sec arrives with a 60° inclination. Diagrams with $\alpha=0, 0.3, 0.5$ along two different cross sections ($h=5m$ and $h=3m$) are given. The treatment of the phase function R are described by Ou and Tzang (1986). The mesh size in the section is $10m$.

In Fig. 5, since the semi-infinite breakwater is permeable, the normalized wave height distributions on diffraction region are no more smoothly decreasing away from the tip. The wave height distributions oscillate with the same phase and the mean wave height increases as α varies from 0 to 0.5. On the contrary, the distributions become more smooth as α increases on incident region. In Fig. 6, for a single permeable detached breakwater, waves behind the breakwater are affected by waves diffracted from the two tips of the breakwater and by waves transmitted through the permeable breakwater. On diffraction region, the wave height distributions

oscillate more regularly but with bigger amplitude when breakwater is permeable. In incident region, the maximum wave height somewhat decreases as α increases, but the wave

Fig. 5 wave height distribution for a semi-infinite breakwater with various values of transmission coefficient ($T_0=10\text{sec}$)

Fig.6 Wave height distribution for a single detached breakwater with various values of transmission coefficient ($T_0=10\text{sec}$)

height distributions oscillate without the tendency of attenuation. This is more obvious on the downwave side than on the upwave side. From the numerical results above, it is seen that as the transmission coefficient α increases, the transmitted waves through the permeable breakwater play a more important role in the wave field behind breakwaters.

5. LABORATORY EXPERIMENTS.

To verify the solutions for waves behind permeable breakwaters, a series of careful experiments are performed in a wave basin (16m×12m). The detail discussion of the laboratory experiments is given by Tzang (1986). A brief summary of the experimental setup is given herein.

As shown in Fig. 7, a plane beach with 1/20 slope is

installed in otherwise constant water depth of 0.4m. The permeable detached breakwater, made of plywood and lumber filled with armor units, as shown in Fig. 8, has a length of 3m for single detached breakwater. Waves are generated by a 9m long flap-type wave maker, which is mobile for changing the direction of wave propagation. Four wave gauges were used to measure the wave height. One is used for the incident wave information in constant water depth. The others are used for the diffracted wave amplitude behind the breakwater. The sections chosen are located at 0.5, 1.0, 1.5, 2.0 m from the breakwater ($h = 15, 12.5, 10, 7.5$ cm, respectively). All 4 gauges were recorded simultaneously along one section, and then to other section. The distance among the three gauges was 25cm. The transmission coefficient α of the permeable breakwater is tested preliminarily in a wave tank. The wave tank is lined up by guidewalls with 3m width in the wave basin. For the incident wave height $H_0=3$ cm and wave period $T=1$ sec, the experimented value of α equals 0.3. The test conditions are given in Table 1.

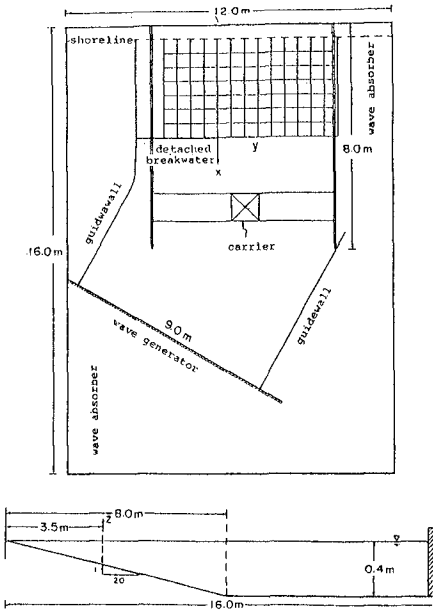

Fig. 7 Sketch of wave basin

Fig. 8 Sketch of permeable breakwater

Table 1. List of Tests Conditions

α	θ_0 (deg.)	BREAKWATER TYPE	BREAKWATER LENGTH (m)	T(sec)	H_0 (cm)
0.3	0°	semi-infinite		1.0	3
				0.8	
		a single detached	3	1.0	
				0.8	
	30°	semi-infinite		1.0	
				0.8	
		a single detached	3	1.0	
				0.8	

Experimental data, obtained by Tzang (1986), behind permeable breakwater for $T=1.0$ sec only are replotted here in Fig. 9 to Fig. 12. In each figure the distributions of wave height are shown for four sections, $h=15, 12.5, 10, 7.5$ cm. Theoretical curves are also included for comparison. In Fig. 9 and Fig. 10 the wave height distribution on diffraction region of semi-infinite permeable breakwater are not attenuating but oscillating. On incident region, the theory usually underpredicts the experimental data. The agreement between theoretical solutions for $\alpha=0.3$ and experimental data in Fig. 10 is reasonably good. But the scattering of the experimental data in Fig. 9 is rather significant. This could be caused by the reflection from the breakwater. In Fig. 11 and Fig. 12 the overall agreements between theoretical solutions and experimental data are quite good except on the incident region far from the origin. This could be partially influenced by the boundaries of the wave basin and partially attributed to the existence of circulations of current (Liu and Mei, 1976). Also, wave reflected from the breakwater will influence the incident waves so as to cause the scattering of the experimental data. This is more obviously for normal incidence ($\theta_0=0^\circ$) than for oblique incidence ($\theta_0=30^\circ$).

6. CONCLUSIONS

Fig. 9 Comparisons between theoretical results of wave height and experimental data ($T_0 = 1.0 \text{ sec}, \theta_0 = 0^\circ, \alpha = 0.3$): a semi-infinite permeable breakwater

Fig. 10 Comparisons between theoretical results of wave height and experimental data ($T_0 = 1.0 \text{ sec}, \theta_0 = 30^\circ, \alpha = 0.3$): a semi-infinite permeable breakwater

Fig. 11 Comparisons between theoretical results of wave height and experimental data ($T_0=1.0$ sec, $\theta_0=0^\circ$, $\alpha=0.3$): a single detached permeable breakwater

Fig. 12 Comparisons between theoretical results of wave height and experimental data ($T_0 = 1.0$ sec, $\theta_0 = 30^\circ$, $\alpha = 0.3$): a single detached permeable breakwater

By employing Hotta's (1978) concepts and extending the asymptotic solutions developed by Liu et al. (1979), we have obtained a simple description of wave height distributions behind permeable detached breakwaters. It is seen that the transmission coefficient α , the wave period T , and the incident angle are all contributed to the wave height variation. Large values of the transmission coefficient α will increase the mean wave height distribution on diffraction region but will not change its phase. It is also shown that, for a larger value of α , the transmitted waves play a more important role than the diffracted waves. The solutions developed in this paper have been reasonably verified by laboratory experiments except on the incident region far from the origin.

CHAPTER 9

INCOMING AND OUTGOING WAVE INTERACTIONS ON BEACHES

Rao V.S.N.Tatavarti*, David A.Huntley†, and Anthony J.Bowen*

A technique to decompose colocated random field measurements of wave elevation and current velocity into incoming (shoreward propagating) and outgoing (seaward propagating) components is presented. This decomposition technique, which is less sensitive to noise, enables us to determine the frequency dependent reflection coefficients and also the relative phase between the incoming and outgoing waves. The method is applied to C^2S^2 and NSTS data sets, from beaches with wide ranging characteristics and wave regimes. The results demonstrate the selective nature of beach absorption/reflection characteristics but are inconclusive in terms of a proper parameterization of reflections on natural beaches.

Introduction

Since the pioneering work of Miche (1951) coastal engineers have generally relied on empirical formulations to determine the reflectivity of a nearshore structure or a natural beach. These formulations, being based on monochromatic wave theories for planar beaches, were primarily designed to yield bulk reflection coefficients. In reality, however, we are faced with a spectrum of incident waves and complicated beach topographies, thus questioning the validity of bulk reflection coefficients. According to Miche's theory the reflected wave height is determined by the maximum wave steepness possible for a non breaking wave on a beach of linear slope. Therefore Miche's hypothesis suggests that there is a f^{-2} dependence of the reflection coefficient R , for monochromatic waves, where f is the wave frequency. This strong frequency dependence suggests that the use of a single bulk reflection coefficient for a spectrum of incident waves will be unsatisfactory. Carrier and Greenspan (1958) suggested that very small reflection coefficients are characteristic of natural beaches for waves of all but the very smallest amplitudes and that standing waves play no important role on such beaches. On the contrary there is ample evidence that standing waves are important on natural beaches (Suhayda,1974; Huntley, 1976; Holman, 1981; Guza and Thornton, 1982; Wright *et al.*, 1982; Bowen and Huntley, 1984; Elgar and Guza,1985) and that steeper beaches are reflective (Wright and Short, 1984).

As beaches have been used in hydraulic laboratories for over a century, it is but natural to focus attention on the laboratory investigations for more information on wave reflections. However, it is surprising to note that these investigations are ambiguous due to a lack of consensus in defining the critical parameters affecting the determination of reflection coefficient, leading to differences in results (Battjes, 1974; Guza and Bowen, 1976) and confusion in understanding the physics. This confusion reflects the difficulty in obtaining reliable measurements of the wave reflections. Moreover there is an additional difficulty of extending these results obtained on the basis of monochromatic wave theories to a spectrum of incident waves naturally found on beaches.

Field investigations of low frequency waves have yielded equally confusing results. Munk (1949) and Tucker (1950) implied that there is a small nonlinear long wave correction under shoreward propagating wave groups and a larger seaward propagating long

* Dept. of Oceanography, Dalhousie University, Halifax B3H 4J1, Canada.

† Institute of Marine Studies, Plymouth Polytechnic, Drake Circus, Plymouth PL4 8AA, U.K.

frequency wave released at breakpoint. In contradiction, Hasselman *et al.* (1963) presented evidence that shoreward propagating nonlinearly forced motion is larger than the seaward propagating component. Suhayda (1974) however, suggested that the incoming and outgoing components are of roughly equal magnitudes indicating that the concept of standing waves is important. The foregoing demonstrates the need to decompose random wave observations into incoming and outgoing components not only to understand clearly the nearshore wave dynamics and resulting sediment transport process but also to quantify the frequency dependent reflection coefficients.

The more recent studies on wave reflections utilize various analytical techniques to resolve a composite wave field into incident and reflected waves using measurements from wave sensors at adjacent locations (Thornton and Calhoun, 1972; Goda and Suzuki, 1976; Isobe and Kondo, 1984; Kim, 1985; Mansard and Funke, 1987).

The technique which is currently used by hydraulic laboratories for separating the incident and reflected spectra from the measured standing wave system in a laboratory is that of Goda and Suzuki (1976). The basic assumptions in this technique are that an irregular sea state can be described as a linear superposition of an infinite number of discrete frequency components, each with their own frequency, amplitude and phase, and that each frequency component travels with its own individual celerity described by the linear dispersion relationship. The technique consists of simultaneous measurements of the composite waves (superposition of incident and reflected) at two or three known positions in a line parallel to the direction of wave propagation. Fourier analysis of these measurements then provides the amplitudes and phases of the frequency components constituting the irregular sea state, on the basis of which the incident and reflected components can be resolved.

Although the technique is applicable to both regular and irregular trains of waves, the resolution into incident and reflected components is effective only outside the condition of the wave sensor spacing being an even integer of half wave length. In other words the resolution technique is strongly affected by the location of the sensors and the spacing between them. Also any nonlinear wave interaction affects the accuracy of the resolution technique.

Isobe and Kondo (1984) utilize the maximum likelihood method to measure the directional wave spectrum in a reflective system and determine the reflection coefficient of a structure in a directional sea. As the resolution power of the maximum likelihood method for a directional wave spectrum depends on the number and arrangement of wave sensors, this methodology cannot be applied where sufficient number of sensors are not deployed and also where the optimal arrangement of sensors is not made. A more serious limitation is the inaccuracy in computing reflectivities due to changing wave conditions with wave frequency and the wave direction.

Kim (1985) attempted to estimate the reflection coefficient of a natural beach by computing a cross correlation function for a wave field consisting of incoming and outgoing waves and comparing it with observed spatial correlation functions. The shallow water wave orbital velocities measured at two locations by current meters can be expressed as a combination of incoming and outgoing components. By analytically deriving an expression for the cross correlation function between the two measurements from the expressions for the combined wave fields at two locations, Kim suggests that cross correlation peaks appear at time lags associated with incoming and outgoing waves. Kim's study provides evidence for the existence of standing waves and seagoing waves at the expected time lags and allows a rough estimation of the relative magnitudes of incident and reflected waves. However, the major disadvantage of using the cross correlation function is that no frequency information can be obtained.

The most recent study on the problem of determining the reflection characteristics of test structures in laboratories was carried out independently by nine laboratories of the IAHR working group (Mansard and Funke, 1987). As the principle used to compute reflection coefficients is based essentially on Goda and Suzuki's theory, there are limitations in obtaining the true reflections. Mansard and Funke (1987), comparing results from various laboratory experiments under similar conditions using the same techniques, conclude that the estimated reflective properties of impervious sloped beaches vary appreciably between different laboratories.

The usual way of addressing the problem of wave reflection from beaches seems inevitably to imply perfect reflection, a direct consequence of the assumed form of the offshore wave field and the conservation of mechanical energy (Carrier and Greenspan, 1958; Meyer and Taylor, 1972). Energy considerations show that wave absorption must be associated with the degradation of mechanical energy through wave breaking. However, in practice it is not possible to make a direct determination of the energy absorption, so this has to be inferred from observations of the wave field. Also there are no rigorous theoretical models to describe the physics of wave breaking on beaches and it is customary to treat breaking as a specific event for each identifiable wave (some recent exceptions to this line of thought are Guza and Thornton, 1982; Symonds *et al.*, 1982, where random waves are considered). Hence we focussed our attention on field measurements in attempting to decompose a random wave field into incoming and outgoing components. Tataavarti and Huntley (1987) and Tataavarti (1987) demonstrate a number of different techniques attempted in order to compute frequency dependent reflections from field measurements and also highlight various advantages and limitations associated with each technique.

Over the past twenty years there has been a very significant increase in the number of field measurements of wave elevations and currents in the nearshore region. It has become customary in recent years to deploy colocated elevation and current meters in the field. Therefore, we decided to estimate frequency dependent reflections utilizing colocated elevation and current measurements.

Data For Analysis

Data collected as part of the C²S² program on two maritime Canadian beaches at Pointe Sapin, New Brunswick, Stanhope Lane, P.E.I.; and NSTS data from Leadbetter beach at Santa Barbara, California (U.S.A) have been used to test the theoretical formulation. Measurements of the flow field were made using colocated Marsh- McBirney electromagnetic current meters and pressure transducers. Each current meter, measuring the two orthogonal axes of the flow with a response time of 0.2 *secs*, was aligned to measure the onshore/offshore and the alongshore components of the flow. The pressure transducers were designed to measure the wave elevation. The field environments comprise plane and barred beaches with wide ranging wave conditions (Table 1). Pointe Sapin (PS62) beach has a mild slope with a steep foreshore. Stanhope Lane (ST12) is a barred beach. Leadbetter (LB7, LB3) beach has a relatively steep slope (Fig.1).

Prior to the decomposition, corrections were made for the filter characteristics of the current meter electronics, the current meter axes have been aligned towards the predominant wave direction and the time series Fourier decomposed into frequency components and each Fourier amplitude multiplied by $(\tanh kh/\omega)$ factor, where k is the wave number, h the water depth and ω the radian frequency. The resulting Fourier amplitudes and the Fourier decomposed phases have been inverse Fourier transformed into the time domain. The output time series of the current measurements (\hat{u}) now have units of meters, consistent with the units of elevation measurements.

Incoming and Outgoing Waves: Time Domain Analysis

Utilizing the linear wave theory, the velocity potential Φ_{io} of near normal incidence shallow water waves may be expressed as a linear superposition of incoming (shoreward propagating) and outgoing waves (seaward propagating) over a flat bottom as follows,

$$\Phi_{i_o} = \frac{g}{\omega} [a \sin(kx - \omega t + \phi_i) + b \sin(kx + \omega t + \phi_o)] \quad (1)$$

where a and b are the amplitudes associated with incoming and outgoing waves respectively, ϕ_i and ϕ_o are the relative phases of incoming and outgoing waves respectively, x is the cross shore coordinate, positive onshore.

If we transform the cross shore velocity ($u = \frac{\partial \Phi_{i_o}}{\partial x}$) into elevation ($\eta = -g^{-1} \frac{\partial \Phi_{i_o}}{\partial t}$) using linear wave theory, then we can express the sum and difference series of elevation and the transformed velocity as incoming and outgoing components,

$$\frac{(\eta + \hat{u})}{2} = a \cos(kx - \omega t + \phi_i) \quad (2)$$

$$\frac{(\eta - \hat{u})}{2} = b \cos(kx + \omega t + \phi_o) \quad (3)$$

where \hat{u} is the transformed u .

Defining the ratio of the amplitude of the outgoing wave to that of the incoming wave as the reflection coefficient R we have

$$R = \left[\frac{\langle (\eta - \hat{u})^2 \rangle}{\langle (\eta + \hat{u})^2 \rangle} \right]^{\frac{1}{2}} \quad (4)$$

where $\langle \rangle$ denotes ensemble averaging. Thus, after obtaining the incoming and outgoing wave series the frequency dependent reflection coefficient can be determined using standard spectral techniques.

Guza *et al.* (1984) have shown that colocated elevation and current meters can be used to decompose measured waves into incoming and outgoing components based on the aforementioned theory. However, there is an important problem associated with this method of estimating the frequency dependent reflection coefficient. A close examination of the coherence estimates of η and u time series and the estimated frequency dependent reflection coefficient plots (Fig.2a and 2b) of the Stanhope Lane data set shows that the reflection plot is almost a mirror image of the coherence plot. At low coherences the reflection coefficient tends to unity. Clearly, if η and u are incoherent, their sum and difference time series, as in equations (2) and (3), will have the same variance so that the apparent reflection coefficient will tend to 1.0. Therefore there is a need to reduce the noise dependence of the reflection coefficient estimates. This led us to search for alternate techniques to decompose the field measurements into incoming and outgoing components.

Incoming and Outgoing Waves: Frequency Domain Analysis

Studies by Oppenheim and Lim (1981) have focussed on the importance of phase in signals. The phase between two signals, computed using the cross spectrum, is only related to the coherent part of the two series and hence should be independent of noise. So spectral phase information obtained from the η and u measurements may be used to obtain incoming and outgoing components and hence determine the frequency dependent reflection coefficients. As discussed in Tatavarti and Huntley (1987) this would require modelling waves over complex topographies naturally occurring on beaches. This is a significant complication. However, in principle one can avoid the necessity for modelling waves over complex topography by calculating, from the time series of η and u at a single location, the gain between the two series in addition to the phase.

Let us now express the time series of colocated measurements of wave elevation and on-offshore current velocity in terms of a modulation function and a carrier function.

$$\eta(x, t) = \Re \{ A(\psi) e^{i\omega t} \} \quad (5)$$

$$\hat{u}(x, t) = \Re \{ B(\psi) e^{i(\omega t + \theta(\psi))} \} \quad (6)$$

where $\eta(x, t)$, is the time series measurement of elevation (m) at an offshore location x , from shoreline.

$\hat{u}(x, t)$, is the time series measurement of the on-offshore velocity at an offshore location x , from the shoreline, normalized such that it has the units of elevation (m).

$A(\psi)$ and $B(\psi)$, are the slowly varying amplitude modulation functions associated with the time series of $\eta(x, t)$ and $\hat{u}(x, t)$ measurements, in which ψ is a function of beach slope, local wave amplitude, wave number and wave frequency.

$\theta(\psi)$ is the phase difference associated with the two time series measurements.

$e^{i\omega t}$, is the carrier wave in which ω is the radian frequency.

In practice the ensemble averaging is often estimated by a frequency band averaging, whose equivalence is supported by the ergodicity hypothesis. Therefore, from a spectral perspective we can rewrite the variance of the incoming waves and the variance of the outgoing waves respectively as per equations (2) and (3) as

$$E_{in}(\omega) = \tilde{A}^2(\omega) + \tilde{B}^2(\omega) + 2\tilde{A}(\omega)\tilde{B}(\omega) \cos \theta_{\eta\hat{u}}(\omega) \quad (7)$$

$$E_{out}(\omega) = \tilde{A}^2(\omega) + \tilde{B}^2(\omega) - 2\tilde{A}(\omega)\tilde{B}(\omega) \cos \theta_{\eta\hat{u}}(\omega) \quad (8)$$

where \tilde{A} and \tilde{B} are the average estimates of A and B over a realization (record length in practice). Writing the gain function as $G(\omega) = \frac{\tilde{A}(\omega)}{\tilde{B}(\omega)}$, we express the frequency dependent reflection coefficient $R(\omega)$ as

$$R^2(\omega) = \left[\frac{1 + G^2(\omega) - 2G(\omega) \cos \theta_{\eta\hat{u}}(\omega)}{1 + G^2(\omega) + 2G(\omega) \cos \theta_{\eta\hat{u}}(\omega)} \right] \quad (9)$$

Equation (9) therefore gives the frequency dependent reflection coefficient in terms of the gain and the phase relationships between η and u measurements.

The phase between two signals, computed using the cross spectrum, is only related to the coherent part of the two time series and hence should be independent of noise. *Hence the key to this method of estimating $R(\omega)$ is to find an estimator for gain, $G(\omega)$, which is insensitive to noise in both η and u measurements.*

Generally, in spectral analysis, the time series of one parameter is designated as a base series and coherence and phase relationships are computed between this series and those of other parameters. There are a number of problems associated with the use of base series. For example, when different waves are present in the same frequency band, there is considerable difficulty in interpreting the cross spectrum data as there is no way of determining how many wave structures are present and what is the relative contribution of each wave type to the variance spectra. Also the use of base series produces a bias in favour of the base series, when computing wave amplitudes. If the coherence between various parameters and the base series is not large, this can result in considerable distortion in the pattern of wave amplitudes. Moreover this does not exploit the information contained in the cross spectra between parameters other than the base series. In order to avoid these problems we resorted to the complex eigenvector analysis suggested by Wallace and Dickinson (1972), where the vector time series is expressed as a linear combination of eigenvectors of the cross spectrum

matrix for frequency bands of interest. To increase the statistical confidence in E.O.F. analysis the colocated alongshore velocity (v) time series is also considered.

Employing complex empirical orthogonal function analysis to reduce noise sensitivity it is possible to determine the reflection coefficients from a spectral perspective utilizing the relation

$$\hat{R}(\omega) = \left[\frac{1 + \hat{G}^2(\omega) - 2\hat{G}(\omega) \cos \hat{\theta}_{\eta\hat{u}}(\omega)}{1 + \hat{G}^2(\omega) + 2\hat{G}(\omega) \cos \hat{\theta}_{\eta\hat{u}}(\omega)} \right]^{1/2} \quad (10)$$

where $\hat{G}(\omega)$ is the gain function, the ratio of the amplitude of the principal mode of the elevation to the amplitude of the principal mode of the on-offshore velocity at that frequency $\hat{\theta}_{\eta\hat{u}}(\omega)$ is the phase difference between the principal modes of pressure and on-offshore velocity.

Figure 2c shows the estimated (using equation 9) frequency dependent reflection coefficients for the Stanhope Lane data set. A comparison of Fig. 2b and Fig. 2c demonstrates the significance of estimating reflection coefficients by the frequency domain analysis as opposed to that using the time domain analysis.

Determination Of The Phase Between Incoming and Outgoing Waves

Let us assume that the signal which a sensor measures at any time t , is a linear superposition of incoming wave and outgoing wave signals. One can always represent the incoming and outgoing wave signals as products of the modulation function and a carrier function. As in the previous section, let us consider a harmonic carrier system ($e^{i\omega t}$),

$$S(x, t) = \Re \{ A(\psi)e^{i\omega t} \} = A_{in}(\psi) \cos \omega t + A_{out}(\psi) \cos(\omega t + \phi(\psi)) \quad (11)$$

where $S(x, t)$ is the signal the sensor measures at time t and location x .

$A_{in}(\psi)$ and $A_{out}(\psi)$ are the slowly varying amplitude modulation functions associated with incoming and outgoing wave signals, in which ψ is a function of beach slope, wave amplitude, wave number and wave frequency.

$\cos \omega t$ is the carrier function for the incoming wave signal

$\cos(\omega t + \phi(\psi))$ is the carrier function for the outgoing wave signal

$\phi(\psi)$ is the phase difference associated with the incoming and outgoing wave signals.

Hence, colocated pressure(elevation) and on-offshore current velocity measurements may be expressed as linear superpositions of incoming and outgoing signals,

$$\eta(x, t) = A_{in}(\psi) \cos \omega t + R(\psi)A_{in}(\psi) \cos(\omega t + \phi(\psi)) \quad (12)$$

$$\hat{u}(x, t) = B_{in}(\psi) \cos \omega t - R(\psi)B_{in}(\psi) \cos(\omega t + \phi(\psi)) \quad (13)$$

where $A(\psi)$ and $B(\psi)$ are the slowly varying amplitudes associated with $\eta(x, t)$ and $\hat{u}(x, t)$ measurements

$R(\psi)$ is the ratio of the outgoing to the incoming wave amplitudes, which can be approximated by the average value of the reflection coefficient for a given realization, usually the length of the record, estimated using equation (10)

Utilizing spectral techniques to compute Fourier coefficients, co spectrum, quad spectrum and phase spectrum the following expression for the phase associated with incoming and outgoing components is obtained,

$$\tan \phi(\omega) = \frac{2\hat{G}(\omega)}{1 - \hat{G}^2(\omega)} \sin \hat{\theta}_{\eta\hat{u}}(\omega) \quad (14)$$

Figure 2. (a) Cross spectral coherence between the wave elevation η and the on/offshore velocity u for Stanhope Lane data (ST12). (b) Reflection coefficient as a function of the frequency using time domain analysis and (c) frequency domain analysis for the same data.

Decomposition Of Random Waves Into Incoming and Outgoing Components

Once the magnitude of the reflection, $R(\omega)$, and the phase associated with reflection, $\phi(\omega)$, are computed it becomes trivial to decompose the random wave field into incoming and outgoing components.

One can express the composite variance that any sensor measurement yields as

$$E(\omega) = A_{in}^2(\omega) + R^2(\omega)A_{in}^2(\omega) + 2A_{in}^2(\omega)R(\omega) \cos \phi(\omega) \tag{15}$$

In other words, the composite variance is the summation of the incoming variance, the outgoing variance and twice the co spectrum of incoming and outgoing components. Therefore, the incoming variance is given by

$$E_{in}(\omega) = \frac{E(\omega)}{\{1 + R^2(\omega) + 2R(\omega) \cos \phi(\omega)\}} \tag{16}$$

and the outgoing variance is given by

$$E_{out}(\omega) = \frac{E(\omega)}{\{1 + R^{-2}(\omega) + 2R^{-1}(\omega) \cos \phi(\omega)\}} \tag{17}$$

If the measured auto-spectral phase of the elevation sensor (computed by spectral analysis techniques) is denoted by θ_η , then assuming that the measured phase is actually a linear superposition of the incoming ($\phi_{\eta i}$) and the outgoing ($\phi_{\eta o}$) phases, it can be shown that

$$\phi_{\eta i}(\omega) = \theta_\eta(\omega) - \tan^{-1} \left[\frac{R(\omega) \sin \phi(\omega)}{1 + R(\omega) \cos \phi(\omega)} \right] \quad (18)$$

and

$$\phi_{\eta o}(\omega) = \phi(\omega) + \phi_{\eta i}(\omega) \quad (19)$$

Using equations (16), (17), (18) and (19) and employing inverse Fourier transform techniques the random series, i.e., the measured time series, can be decomposed into incoming time series and outgoing time series as shown in Figure 3.

Figure 3. Flow chart demonstrating the technique employed to decompose random waves into incoming and outgoing components.

Observations and Discussion

Standing waves can either exist as leaky modes or trapped modes. Leaky modes are the two dimensional waves with the fluid motion normal to the shore and uniform alongshore. The trapped modes are the three dimensional edge waves trapped in the nearshore by refraction and periodic alongshore, with both shore normal and shore parallel components. The present technique of decomposition only considers the leaky waves. A review of the pertinent literature points out the difficulties previous researchers (Huntley, 1976; Holman

et al., 1978; Oltman-Shay and Guza, 1987) faced in distinguishing between the edge waves and leaky waves, even with observations from cross shore and longshore arrays of instruments located in the nearshore region. This is clearly indicative of how formidable, if not intractable, the problem of distinguishing edge waves from leaky waves can be. Utilizing the fact that the key distinction between edge waves and leaky waves lies in their directions of progress, with edge waves propagating alongshore and leaky waves propagating primarily on-offshore, the energy levels in the cross shore (u) and the alongshore (v) components of velocity measurement should provide an indication of the presence or absence of edge waves. The ratio of the energy in the v component to that of the u component of the horizontal velocity being larger in the presence of edge waves than in the presence of near normal incidence leaky waves alone. The ratios of variances [$\langle v^2 \rangle / \langle u^2 \rangle$] in Table 1 suggest that Pointe Sapin and Leadbetter beach data may not be seriously contaminated by edge wave motions. For Stanhope Lane beach data, however, the ratio is indicative of a significant contribution of energy from low mode edge waves.

Figure 4 shows the reflection coefficient estimates as functions of frequency for the different beaches. The most prominent feature that stands out in Fig. 4 is that the low frequency waves are strongly reflective while the wind wave frequencies are progressive onshore. This is consistent with earlier studies by Suhayda (1974), Huntley (1976), Bowen (1980), Holman (1981), Wright *et al.* (1982), Guza and Thornton (1982), Bowen and Huntley (1984), and Elgar and Guza (1985); who suggested that low frequency energy occurs in the form of cross shore leaky waves. The similar frequency dependent reflection coefficient plots for the data from different locations on the Leadbetter beach suggests the insignificant role of edge wave motions in these measurements and demonstrates the ability of this technique to minimize the influence of noise.

Figure 5 shows the relative phase between incoming and outgoing waves as a function of the frequency. For any incoming wave the outgoing wave can either be i) the reflected component, ii) any wave generated by some mechanism (for example, Symonds *et al.*, 1982) inside the zone between the sensor and the shoreline or iii) a combination of both. The more or less linear phase with frequency observed in Fig. 5 suggests that the outgoing waves are mostly the reflected waves. The linear phase is also consistent with the nondispersive time lag (considering only low frequencies) associated with a shoreline reflection for Pointe Sapin and Leadbetter beaches. Stanhope Lane beach of course, being a barred beach, further complicates the interpretation of the incoming/outgoing phase difference because of the distinct possibility of multiple reflectors (Tatavarti, 1987).

Figure 6 shows the decomposed incoming and outgoing spectra against the measured elevation spectra. As one would expect *a priori*, the outgoing variance is significantly smaller than the incoming variance, except in the low frequency region. It is clear that the low frequency outgoing energy is statistically significant. This feature has also been indicated in the frequency dependent reflection coefficient plots. Thus the primary region of interest for decomposition seems to be the low frequency band of the wave spectra.

The ability to decompose the observed wave field into incoming and outgoing components suggests that one can quantify the relative magnitudes of the incoming and outgoing components and determine whether the outgoing long wave is a simple reflection of the incoming long wave. Of future interest would be the question of the origin of the outgoing long waves. If the outgoing long waves are simple reflections of the incoming long waves then at what location on the beach are these waves being reflected? *i.e.*, Is there any particular region on the beach topography which effectively reflects the long waves?

Figure 7a shows the smoothed reflection coefficient as a function of the wave frequency for data from different beaches (Pointe Sapin, Stanhope Lane, Leadbetter) and at different locations on the same beach (Leadbetter). It is clear that the barred beach data set (ST12)

Figure 4. Frequency dependent reflection coefficient estimates obtained using equation (14) for (a) Pointe Sapin data set (PS62), (b) Stanhope lane data set (ST12), (c) Leadbetter data sets (LB7) and (d) LB3.

shows remarkably different characteristics from the planar beaches suggesting the influence of the beach slope on the reflection coefficient estimates. Figure 7b shows the reflection coefficients for data from different beaches and at different locations as a function of the Iribarren number ($\epsilon = \frac{2a_o \omega^2}{g \tan^2 \beta}$). From Fig. 7b it is evident that inclusion of the beach slope did bring the reflection curve of ST12 data set towards the general trend shown by the other data sets. However, the inclusion of the record average wave amplitude for a_o , in the case of Leadbetter data set has not reduced the scatter in the curves. It is not clear whether to use a frequency band averaged amplitude or a representative record averaged amplitude for a_o in the expression for ϵ . A frequency band averaged amplitude would be meaningless if the waves in that frequency band are breaking. This problem of extending the monochromatic wave results to a spectrum of incident waves naturally found on beaches is a general one for which no satisfactory solution exists.

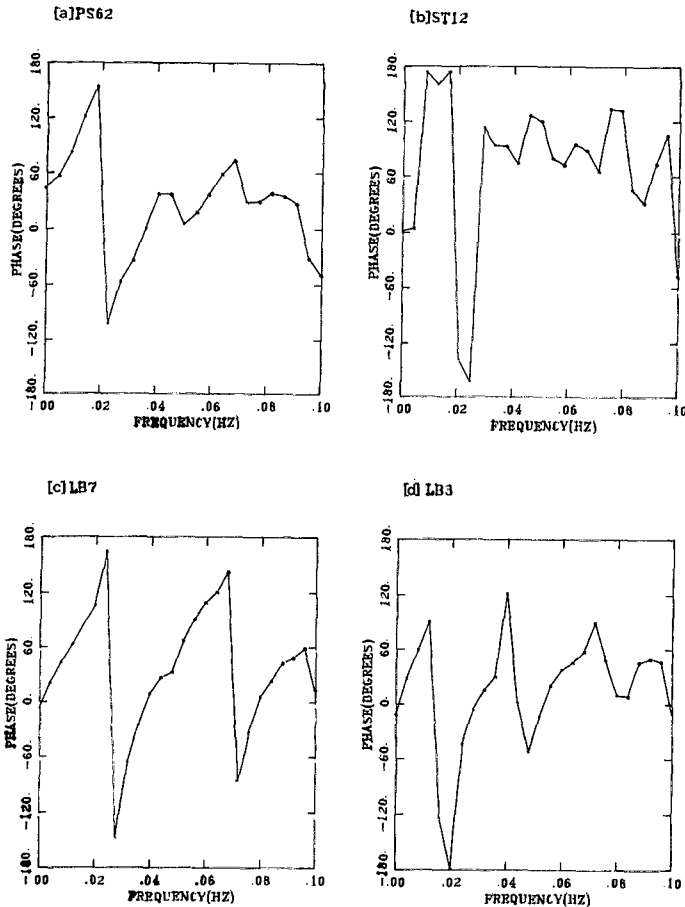

Figure 5. Relative phase between incoming and outgoing waves as a function of the frequency obtained using Equations (19) and (20) for (a) Pointe Sapin data set (PS62), (b) Stanhope Lane data set (ST12), (c) Leadbetter data sets (LB7) and (d) LB3.

Conclusions

- i) Use of colocated velocity and elevation measurements avoids the resolution problem associated with the more common method of spatially separated sensors.
- ii) Our technique minimizes the influence of noise, which tends to drive the reflection coefficient towards unity.
- iii) The technique also gives the relative phase between incoming and outgoing waves and leads to decomposition of the original time series into time series of incoming and outgoing waves.
- iv) Results from different beach sites and different wave conditions confirm that the re-

flection coefficient is high at low frequencies but usually becomes very small at high frequencies.

- v) The shape of the frequency dependent reflection coefficient appears to depend strongly on the shoreface beach slope, but the influence of wave amplitude is less clear.

CHAPTER 10

WAVE RUN-UP ON A NATURAL BEACH

Mitsuo Takezawa¹, Masaru Mizuguchi²

Shintaro Hotta³ and Susumu Kubota⁴

ABSTRACT

The swash oscillation, waves and water particle velocity in the surf zone were measured by using 16 mm memo-motion cameras and electromagnetic current meters. It was inferred that incident waves form two-dimensional standing waves with the anti-node in the swash slope. Separation of the incident waves and reflected waves was attempted with good results using small amplitude long wave theory. Reflection coefficient of individual waves ranged between 0.3 and 1.0. The joint distribution of wave heights and periods in the swash oscillation exhibited different distribution from that in and outside the surf zone. This indicates that simple application of wave to wave transformation model fails in the swash zone.

1. INTRODUCTION

The understanding of wave dynamics in the swash zone on natural beaches is important for understanding beach erosion, designing coastal structures, estimating beach deformation after construction of structures, and so on. However, the properties of swash waves are not well understood. Clarification of the wave characteristics is difficult because field observation of waves in the swash zone are difficult to perform. Only a few measurements are reported (Guza and Thornton, 1982; Mizuguchi, 1984; Holman and Sallenger, 1985).

For measurement of waves in the swash zone, the visual method, in which the water surface profile is recorded by camera or video movie camera, and the electrical method, in which resistance-type or capacitance-type wave gages are employed with some modification for the limited use, have been employed (Holman and Guza, 1984). The authors here use both methods for measuring waves in the swash zone, with improvements, and have developed a technique that combines the two method together.

The method developed is an electrical technique utilizing a capacitance-type wave gages, a wave run-up meter, stretched parallel to and about 2 cm above the sand surface, and monitoring of the water surface at marker sticks installed in the swash zone using video-movie cameras or 16mm memo-motion cameras. An advantage of this method is that the record can be supplemented with data form the cameras when the run-up meter malfunctioned.

Field observations were carried out at three different locations Chigasaki, Oarai, and Hasaki Beaches. The field experiment conducted at Chigasaki Beach (facing the Pacific Ocean and located about 50 km southwest of Tokyo) was a preliminary one, and only limited results were obtained as shown in the Conference ABSTRACT. Based on the experience gained in the preliminary experiment, the measuring method was improved and successfully employed in observations at Oarai and Hasaki Beaches. The purpose of present paper is to describe the measuring method, the analysis procedures applied to the data, and their results. More data were obtained than presented in this paper. Only the results fom at Oarai Beach will be described and discussed in this paper. These data were obtained using a remote sensing photographic technique utilizing synchronized 16 mm memo-motion cameras which film the water surface on marker sticks at a fixed time interval.

II FIELD OBSERVATION

Field observation was carried out on July 29, 1987, at Oarai Beach located about 200 km north of Tokyo and facing the Pacific Ocean (Fig. 1). Oarai Beach is bounded by a harbor at its northern end. Groins were constructed for protecting the harbor from contamination by intruding sand from the south. Sand accumulats at the southside of groins and erosion is occurring in an area approximately 2 km south of the largest groin. The observation site was located approximately 1.8 km south of the largest groin (see Fig. 1).

Figure 2 shows the sea bottom topography, and arrangement of instrumentation. In the swash zone vertical target sticks made of iron bar, painted white, were installed normal to the shoreline at an interval of 50 cm (see Fig. 3). A total of 41 sticks were installed covering the entire swash zone.

Fig. 1 Location map of field site.

Fig. 2 Beach profile, plan, and arrangement of instrumentation.

A scaffold for photographing waves from the side was erected at the midpoint of the swash zone approximately 40 m south of the stick array. Swash oscillations of the water surface along the array were photographed by two pairs of 16 mm cameras placed on the scaffold. Each camera pair photographed a 10 m section of the swash zone. Five target poles (St. 1 to St. 5 in Fig. 2) were also installed for wave measurement. The sea water surface movement at the poles were recorded by two pairs of cameras mounted on another scaffold constructed on berm. All four pairs of 16 mm cameras were synchronized. The shooting interval was 0.2 s.

A run-up meter was also employed to measure the swash oscillation. The run-up meter was essentially a capacitance-type wave gage, but the measuring range was modified for run-up measurements. The capacitance wire was installed parallel to, and about 50 cm north from, the stick array. The wire was held at a constant height of 2 cm above the sand surface by supporting rods installed at an interval of 2 m. As it was crucial to keep the fixed space of 2 cm during the observation, a couple of man was engaged in for adjusting the height of supporting devices of the capacitance wire. A capacitance-type wave gage and a two-component electromagnetic current meter (EMCM) were attached to filming target poles at St. 4 and St. 5. Photograph 1 shows the stick array and the run-up meter.

The data collection was started at 16:10 and ended at 17:50, giving a 100 min. experiment duration. During the experiment the tide rose about 20 cm. Average breaking wave height and period by visual observation were 1 m and 12 s. Average breaker line was located between Sts. 2 and 3. The type of breaker was plunging and the wave direction was almost normal to the shoreline.

Output of the electrical instrument was recorded on an open-reel digital data recorder. The data sampling interval was 0.2 s. Synchronization between the camera system and data recorder was done by hand. The time lag between both data series was 0.4 s.

Sand in the swash zone was collected at four locations along the array. Sieve analysis indicated the sand was well-sorted with a median diameter of 0.43 to 0.52 mm, sorting coefficients of 1.20 to 1.32, and skewness of 0.92 to 1.11.

III RESULTS AND DISCUSSION

The measuring instruments worked well throughout the experiment except for a capacitance-type wave gage attached to St. 4 which experienced mechanical trouble after installation. The tape was directly loaded onto a main-frame computer and data were transferred to disk for analysis. The data of the 16 mm photographs were first transferred to a personal computer floppy disk using a 16 mm film

analyzer and an ultrasonic digitizer graph pen system. The data were then transferred to computer disk for convenient analysis. The water edge of the swash zone in the 16mm film was read as the horizontal distance from a reference point. Then the distance was transferred to a vertical distance by assuming the swash zone face was a compound slope consisting of three straight slopes (Fig. 3). The swash oscillation was also measured by the run-up meter. A comparison of data by 16 mm film and by the run-up meter showed the same results as already reported by Halman and Guza(1984). The wave data by 16 mm cameras and by electromagnetic current meters are used in this paper.

3.1 Raw Data

Figure 4 shows a portion of sea water surface records from St. 1 through St. 5 and the swash oscillation. We can easily recognize the crests of primary individual waves (Mizuguchi, 1982) at each measurement point. However, at St. 4 and St. 5, in the surf zone, there small waves appear, which are not observed at St. 1. These waves were generated mainly due to breaking. In addition we could clearly observe small outgoing waves by viewing the film. Some of small waves recorded at St. 4 and St. 5 are these reflected waves.

Figure 5 shows power spectral density functions of the sea water surface variation at St. 1 and St. 5, and the swash oscillation. The main power, which lies in the range from 0.03 Hz to 0.2 Hz ($0.03 \text{ Hz} < f < 0.2 \text{ Hz}$, where f is frequency.), decreases considerably from St. 1 to St. 5. However, power in the high frequency range at St.5 increases almost five times that observed at St. 1. This change of power spectral function, which means energy transfer from the peak frequency range to the higher frequency range, is due to the wave breaking. Power in the high frequency range of swash oscillation reduces down to almost the same magnitude of that at St. 1 and power in the frequency range lower than about 0.2 Hz increases greatly. This implies that the low frequency waves form standing waves which have an anti-node in the swash zone. At St. 5, peaks and deep depressions in the power density function alternately appear. However this alternate change of power is not observed in the swash oscillations. Figure 6 shows the cross spectral density function between the sea surface elevation and the on-offshore component of water particle velocity at St. 4. An abrupt fall in coherence and a sudden change in phase function at corresponding frequencies are characteristic features of two-dimensional standing waves (Hotta, Mizuguchi and Isobe, 1981). No significant power was found in the longshore velocity.

The gradient of power density function in the saturated range at the high frequency side of the peak follows -3 power of the frequency (f^{-3}) at the outside of the breaker zone (Sawaragi and Iwata, 1980) and follows -4 power of frequency (f^{-4}) inside the surf zone, as reported by Mizuguchi(1984), and Mase and Iwagaki(1984).

Fig. 4 Example of raw data.

Fig. 5 Power spectral density functions.

Fig. 6 Cross spectra between surface elevation and on-offshore component of water particle velocity at St. 4.

3.2 Wave Height and Period Distribution

For the study of waves, the wave-to-wave method by zero-crossing analysis was employed. The zero-crossing method was applied to raw data, data that a mean sea water level trend due to the tide was identified with the assumption of a parabolic curve, and tide trend was removed (Hereafter referred to as adjusted data), data that were then processed a high pass filter with cut off frequency of 0.045 Hz (Hereafter referred to as filtered data). The filter utilized is given in Fig. 6 of Mizuguchi (1982). Before discussing the results, we note the accuracy of wave data. Wave data obtained by means of 16mm cameras contain error of ± 2 cm in elevation. Therefore, waves lower than 6 cm in height were ignored in analysis (see Hotta and Mizuguchi, 1980).

Figure 7 shows the distributions of wave height and period defined by zero-down crossing method for raw, adjusted, and filtered data at St. 1, St. 4, and the swash oscillation. The number of big waves having large height and long period decreases and the number of small waves having relatively small height and short period increases in order when moving from to raw, adjusted, and filtered data. This can be explained by the effect of the tide and long period fluctuations of the sea water surface on the waves in the nearshore zone. The removal of the tidal trend and the long period fluctuations of sea water surface results in an increase in the number of waves defined by the zero crossing method. Figure 8 compares the wave height distribution of the filtered data by the zero-up and the zero-down crossing methods. Figure 9 shows the joint distribution of wave height and period for the filtered data. Table 1 gives statistically representative waves of the filtered data by zero-down crossing method.

Station 1 is located in the outside of the breaker zone and St. 4 is located in the surf zone. Typical features of wave height and period in the nearshore zone are presented in Figs. 8 and 9. It is seen that the marginal distributions of wave height and period outside of breaker zone is quite similar to the Rayleigh distribution, though the peak shifts to the smaller side. The marginal distributions of the wave height becomes bi-modal and the joint distribution exhibits two maxima in the surf zone. This tendency is particularly strong if waves are defined by the zero-down crossing method (Hotta, Mizuguchi and Isobe, 1982).

It appears that the wave height and period of the swash oscillation is similar to the Gaussian distribution about the mean wave height. However, detailed examination of the joint distribution indicates that the marginal distributions of the wave height and period become bi-modal, and the joint distribution exhibits two maxima if the waves are defined by the zero-up crossing method. This means that big waves often are preceded by relatively small waves in the

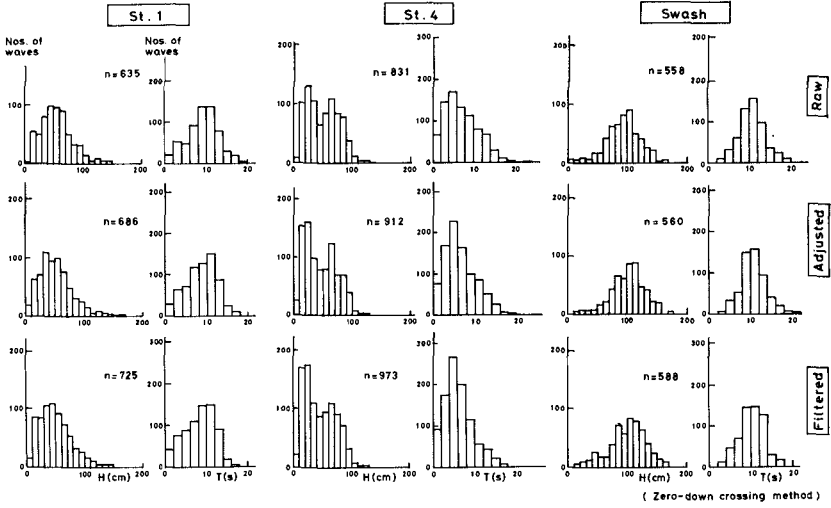

Fig. 7 Wave height and period distribution.

Fig. 8 Comparison of wave height distribution by zero-up and zero-down crossing method.

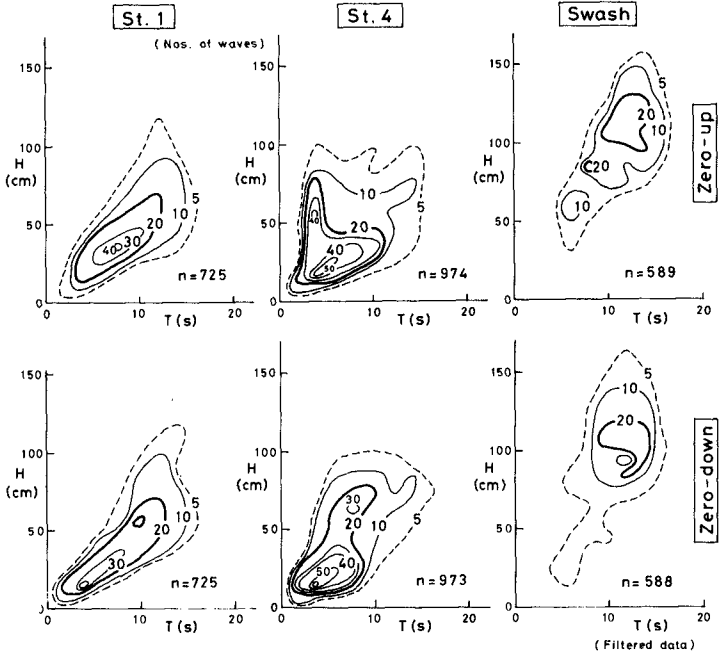

Fig. 9 Joint distribution of wave high and period.

Fig. 10 Example of resolved incident and reflected waves.

swash zone. It is often observed that a larger wave following a smaller preceding wave travels faster, catches up, and passes the preceding wave when the wave is running up on the swash slope.

3.3 Reflected Waves

In section 3.1, indications that waves in the inner surf zone form two dimensional standing waves, during this experiment were given. Separation of incident waves and reflected waves was tried. After Guza, Thornton and Holman (1984), the linear small amplitude long wave theory was applied. That is

$$\eta_{IN}(t) = (\eta + \alpha (h/g)^{1/2} u) / 2 \dots\dots\dots (1)$$

$$\eta_{OUT}(t) = (\eta - \alpha (h/g)^{1/2} u) / 2 \dots\dots\dots (2)$$

where η_{IN} and η_{OUT} are the water surface elevation of incident and reflected waves, u is the on-offshore component of water particle velocity, g is the acceleration due to gravity, h is the water depth and α is a constant. The constant α theoretically takes the value of unity. However the data contained some experimental error. Therefore using the power value in cross spectral analysis between η and u , the most suitable value of α was selected in order to accomplish the separation.

Figure 10 shows examples of the result. The period of the record shown in Fig. 10 corresponds to that in Fig.4. The upper two plots give the separated incident waves at St. 4 and St. 5. The lower two plots give the reflected waves. The middle plot is the swash oscillations (run-up waves) in the swash zone. The broken lines in Fig.10 identify individual waves. Figure 10 shows that incident and reflected waves propagate with the same celerity between two measuring stations. Figure 11 shows the cross-correlation functions between incident and reflected waves. The maximum correlation coefficients are found at a time lag of 10.2 s at St. 5 and 16.4 s at St. 4. The wave celerity between St. 4 and St. 5 estimated from the above two values agreed well with that calculated from the linear small amplitude long wave theory, taking the average value of water depth between St. 4 and St. 5. Figure 11 also shows that a wave group consisting of two or three individual waves is combined into a single wave in the swash zone and is reflected to the offshore. This is popularly observed at natural beaches.

Finally reflection coefficient of individual waves, defined by a ratio between reflected wave height and incident wave height (H_{OUT}/H_{IN}), was examined. Reflection of irregular waves on natural beaches have been dealt with in the frequency domain. However, reflection on a foreshore slope is the result of run-up and run-down of each individual waves. The reflection coefficients in the time

(filtered data, zero-down crossing method)

domain is only an artifice, for which it is difficult to attach any physical meaning.

Figure 12 shows a plot of reflection coefficients against the local wave steepness, defined by the ratio between the incident wave height to the shallow water wave length calculated from the reflected wave period. The solid curve in Fig.12 gives the result of reflection coefficient obtained by Battjes (1974) for the regular waves with beach gradient of one-seventh ($\tan \beta = 1/7$). There is a tendency that reflection coefficients are inversely proportional to the local wave steepness as found in the case of regular waves. However values of ratio in irregular waves are much greater than those given by Battjes (1974). This is because the wave height and period were measured in the deeper offshore area in the laboratory experiment, which support Battjes' formula. The reflection coefficients at St. 4 are generally greater than those at St. 5. Physically it is reasonable that the reflection coefficient at St. 5 should be greater than that at St.4 since St. 5 is located nearer to the shoreline. The opposite result in Fig. 12 may result from the fact that the incident waves at St. 5 had sharp peaks due to nonlinear shoaling. The mean reflection coefficient defined by the ratio of rms value of water surface elevations of reflected waves to that of incident waves is 0.67 at St. 4 and 0.93 at St. 5.

Figure 13 shows a plot of reflection coefficients against the deep water wave steepness. The solid curve denotes Battjes' criterion and the broken curve gives Miche's criterion (Miche, 1951, or Horikawa, 1978). Considerable scatter of data makes it difficult to draw conclusions from Fig. 13 except that the magnitude of reflection coefficient of individual waves in irregular waves is comparable to those for corresponding regular waves.

IV CONCLUDING REMARKS

Field data of swash motion of good quality is obtained by a photographic method. Wave data in and outside of the surf zone were measured simultaneously. Analysis in the frequency domain shows that most of the power in the inner surf zone is of standing waves. However wave to wave analysis is better to describe the waves both in the surf zone and in the swash zone.

Zero-crossing methods are applied to define the individual waves. It is revealed that the number of waves changes considerably when waves propagates from outside the surf zone through the surf zone to the swash zone. This indicates that simple wave to wave method fails to describe the transformation of waves.

Joint distribution of height and period of swash oscillation is obtained. Marginal distributions of wave height as well as period is

similar to Gaussian distribution. Physical interpretation of these facts are left in future. It, however, can be pointed out that nearly constant power in the low frequency range in the swash spectrum might be related to the shape of distribution.

Incident waves and reflected waves are decomposed by using measured surface elevation and cross-shore velocity under the assumption of the linear long wave theory. The decomposed surface elevation profiles show it possible to identify incident waves (or groups of incident waves) and the corresponding outgoing (reflected) waves. Crude estimate of reflection coefficients of these individual waves is attempted. The values are inversely proportional to the local wave steepness in the inner surf zone, and of the same magnitude as those given by Miche formula for monochromatic waves, though the data scatter is rather large.

Reflected waves can be seen as those generated in the swash zone by the incoming waves. It will be a next problem to find out the relationships among the incoming waves, the swash oscillation and the outgoing waves. The problem would be best treated in the physical time domain.

ACKNOWLEDGEMENT

We would like to express our appreciation to the our university students who supported the field work and digitized the films. Without their help we could not have carried out this field research. We gratefully acknowledge the assistance of Dr. S. A. Hughes of the Coastal Engineering Research Center, WES, in the preparation of the manuscript.

CHAPTER 11

Characteristics of Diffusion and Aeration due to Wave Action near Permeable Breakwaters

Hitoshi MURAKAMI* and Yoshihiko HOSOI**

Abstract

This paper deals with the effect of wave action on the water purification near a permeable breakwater. When determining standards for water purification, three indexes are usually taken into account: the diffusion coefficient, the concentration reflection ratio and the reaeration coefficient.

In our study, the values of the diffusion coefficients K_x near the breakwater ranged from about $10^{-1} \text{ cm}^2/\text{sec}$ to $7 \times 10 \text{ cm}^2/\text{sec}$. The effect of aeration caused by setting up a permeable breakwater was limited to within a distance of only one wave length at either side of the breakwater. As a result, values of the reaeration coefficients were then estimated to be in the order of $10^{-5} - 10^{-4}/\text{sec}$.

1. Introduction

In recent years, many legitimate plans for harbor and coastal zone developments have been proposed in succession, e.g, the construction of an artificial island, respective steam and wave force power stations etc. Breakwaters which would protect these facilities must therefore be built in increasing numbers.

However, in response to the recent social demand for better environmental conditions, we are also aware that greater efforts should be made to prevent water pollution in these harbor areas.

jyosanjima, Tokushima, 770, Japan.

** Associate Professor, Technical college, The University of Tokushima.

As a result, the need to design a multipurpose breakwater is required. This means a breakwater effective not only for the reduction of incident wave energy but also for water purification through a permeable wall. The hydraulic characteristics of various kinds of permeable breakwater models have already been investigated both theoretically and experimentally. We also have discussed the effective cross section geometry of the vertical slit-type breakwater from viewpoints of both the hydraulic and water exchange discharge due to the wave action (Murakami et al., 1986).

In addition we may expect a diffusion and aeration function for a permeable breakwater, because of waves which break causing water turbulence along the permeable wall. Although we observed this function, a satisfactory discussion could not be presented in the preceding study.

The purpose of this study is to examine the effect of the vertical slit-type breakwater on water purification paying special attention to the functions of diffusion and aeration.

2. Diffusion Characteristics

2.1 Experimental apparatus and procedure

Models of the vertical slit-type breakwater in this study are shown in Fig.1. A wave tank equipped with a flap-type wave generator at one end and measuring $15\text{m} \times 18\text{cm} \times 30\text{cm}$ was used. The models were placed at a distance of 10m from the wave generator. The water depth h and the wave period T were kept at a constant of 15cm and 0.75sec, respectively. Consequently the wave length L was 75cm. Incident wave steepness H/L was maintained at a value of 0.02.

In the diffusion experiment, a drop of methylene-blue solution was directly introduced as a tracer at the point located one wave length L from the front wall of the breakwater as shown in Fig.2. Periodical changes in concentration of the tracer were measured at two points, one at $L/3$ and the other at $2L/3$. Tests were performed on both the seaward and shoreward side of the breakwater.

Experimental conditions on the diffusion of the contaminant are represented in Table.1.

Fig.1 Horizontal cross sections of vertical slit-type breakwaters

Fig.2 Definition sketch and coordinate system

2.2 Analysis method on diffusion characteristics

The diffusion of a tracer near a permeable wall in a relatively narrow wave tank can be assumed to be a one dimensional diffusion phenomenon.

The diffusion equation on the concentration of tracer C with time factor t and in a given space x is given as follows,

$$\frac{\partial C}{\partial t} = K_x \frac{\partial^2 C}{\partial X^2} \tag{1}$$

where K_x is the one dimensional diffusion coefficient. When the tracer material is introduced at the point x, the solution in Eq.(1) is easily obtained at an arbitrary point x under the following initial and boundary conditions,

$$\left. \begin{aligned} C(0,0) &= \infty \\ C(x,\infty) &= 0 \\ \int_{-\infty}^{\infty} C(x,t) dx &= M \end{aligned} \right\} \tag{2}$$

$$\begin{aligned}
 C(x,t) &= \frac{M}{2\sqrt{\pi K_x t}} \left\{ \exp\left\{-\frac{(x-x_0)^2}{4K_x t}\right\} + r \exp\left\{-\frac{(x+x_0)^2}{4K_x t}\right\} \right\} & x > 0 \\
 C(x,t) &= \frac{M}{2\sqrt{\pi K_x t}} (1-r) \exp\left\{-\frac{(x-x_0)^2}{4K_x t}\right\} & x < 0
 \end{aligned} \quad (3)$$

where M is the mass of the introduced tracer material, r represents the concentration reflection ratio due to the existence of a breakwater, $r=1$ indicates the impermeability of the breakwater and $r=0$ signifies that no breakwater has been installed. Thus we can consider r as an index representing the water quality exchange through the permeable wall. We can clarify the diffusion mechanism from Eq.(2) only if the values of the diffusion coefficient K_x and r are to be correctly estimated. By using the simplex method, we derived values for K_x and r , in which the calculated values of the tracer concentration in Eq.(2) most resembled the observed values of the concentration.

As a result of estimating K_x and r by using the simplex method, we obtain the most approximate curve to the experimental values as seen in Fig.3.

Values of K_x and r for each experiment are shown in Table.2. The lack of values for K_x and r in Table.2 means that unrealistic values for both had been obtained during the course of analysis.

2.3 Consideration of K_x and r

From Table 2, it became evident that values of the diffusion coefficient near a breakwater fall in the range of $10^{-1} \text{cm}^2/\text{sec}$ to $7 \times 10 \text{cm}^2/\text{sec}$. Generally speaking, the value of K_x is greater on the seaward side of a breakwater compared to that of the shoreward side; the value in GC and CE type breakwaters obtained particularly large values.

We would like to discuss the characteristics of K_x and r in more detail. We can only conjecture that the diffusion characteristics near a breakwater will be effected by the turbulence caused by an opening in a permeable wall. The rate of wave energy dissipation at the opening of this wall ε is expressed as follows;

$$\varepsilon = 1 - r_R^2 - r_T^2 \quad (4)$$

Fig.3 Concentration change of tracer

Fig.4 Dependence of diffusion coefficient of the seaward side on energy dissipation rate

where r_R is the reflection coefficient which is defined by the ratio of the reflection wave height H_R to the incident wave height H_I and r_T is the transmission coefficient H_T/H_I (H_T : transmission wave height).

Fig.4 shows the relationship between Kx on the seaward side of the breakwater and the rate of wave energy dissipation ϵ . Here, we notice a tendency emerge, where values of Kx increase concomitantly with an increase in the value of ϵ .

Likewise, on the shoreward side of the breakwater, the values of Kx increase with the increase in the value of the transmission coefficient r_T as shown in Fig.5. Under the condition where the constant value of the incident wave steepness at the wall opening is larger, values of Kx on both seaward and shoreward sides are greater as shown in Fig.6. In Fig.6 the opening ratio is defined by $D/D+B$ as shown too in Fig.1.

Fig.5 Dependence of diffusion coefficient of the shoreward side on wave transmission coefficient

We may infer that the effect due to the existence of a breakwater on the diffusion coefficient will be limited to a small area close to the breakwater.

Next, let us consider the characteristics of the concentration reflection ratio r .

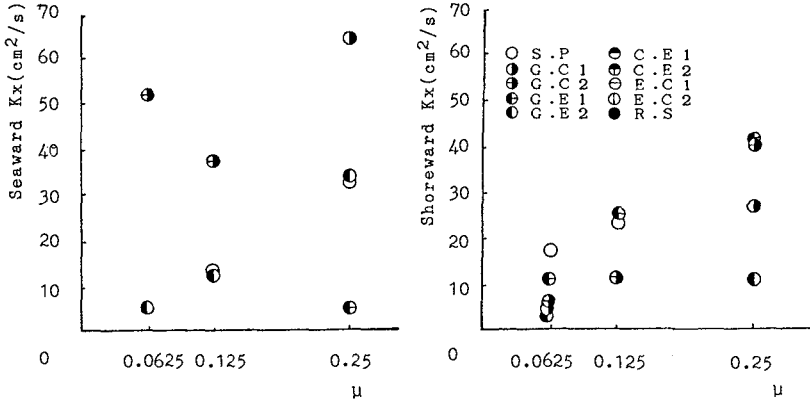

Fig.6 Dependence of diffusion coefficient on opening ratio of permeable wall

Fig.7 Dependence of concentration reflection ratio on opening ratio of permeable wall

Fig.7 shows the relationship between r on both sides of the breakwater and the opening ratio μ . As the opening ratio μ increases, values of r will similarly increase on both sides. This means that if a large opening in the permeable wall occurs, the contaminant near the breakwater will easily flow back with less dilution, regardless of its initial location. According to this inference, as the concentration reflection ratio r on the shoreward side is larger, the diffusion function on the seaward side must decrease, because the contaminant on one side can not easily flow out through the opening to the opposite side of the breakwater. The tendency in Fig.8 supports this suggestion.

Fig.8 Relationship between concentration reflection ratio and diffusivity of the opposite side

3. Reaeration Characteristics

3.1 Experimental apparatus and procedure

The experiment on reaeration was carried out in the same wave tank and the same breakwater models were used as in the diffusion experiment. The range of the incident wave steepness H/L was extended from $H/L=0.01$ to 0.05 . After the concentration of dissolved oxygen in the wave tank was compulsorily reduced by sodium sulfite, a wave was generated for one hour to observe the concentration change of the dissolved oxygen. The concentration of the oxygen was measured at time intervals of 15 minutes and values of concentration change for each location were estimated at 50cm apart from each other. The origin of these observation points was situated in the rear wall of the breakwater and is represented by zero on the abscissa.

Fig.9 shows some examples of spatial concentration distribution of the dissolved oxygen over certain periods of time for four breakwater types. The region containing the minus sign in these figures represents the seaward side of the breakwater. The abbreviation P.I on the right hand side of the lower figure stands for an impermeable plate, in this case the concentration change depends only on the aeration caused by the standing wave. Apart from this exception, the concentration of dissolved oxygen increases remarkably with time in the restricted area near to the breakwater.

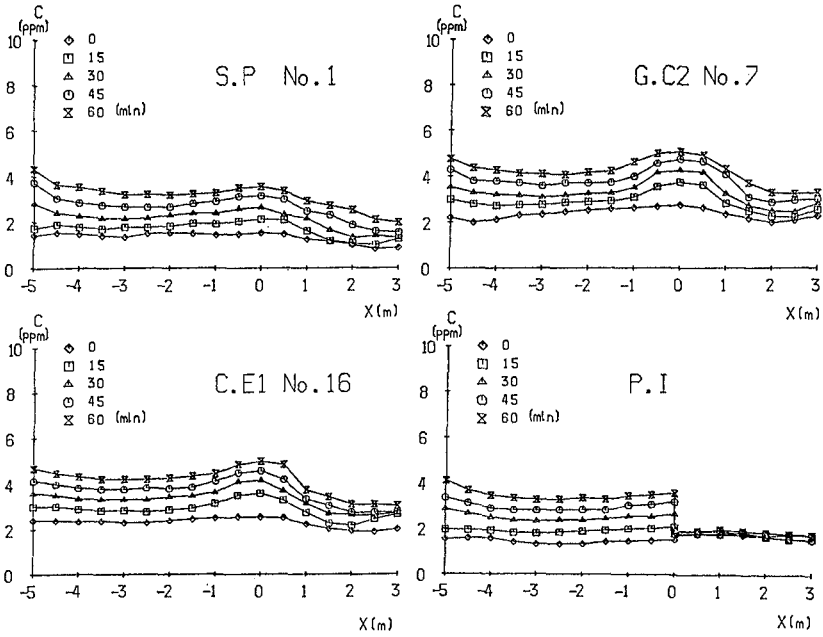

Fig.9 Spatial concentration distribution of dissolved oxygen near breakwater

3.2 Reaeration Coefficient

We shall explain the mechanism of reaeration briefly. Reaeration compensates for the deficiency in oxygen levels through the water surface exposed to the atmosphere. As shown in Fig.9, reaeration efficiency near the breakwater is greater than that in other areas. The mass conservation equation relating to the dissolved oxygen can be written as follows:

$$\frac{dC}{dt} = K_L \frac{A_S}{V} (C_S - C) \quad (5)$$

where C and C_S represent the dissolved oxygen concentration and its saturation value respectively. K_L indicates the mass transfer coefficient, A_S and V are surface area and water volume respectively.

The reaeration coefficient k_2 which represents "the aerateability", is defined as follows.

$$k_2 = K_L \frac{A_S}{V} \quad (6)$$

Then Eq.(5) is rewritten

$$\frac{dC}{dt} = k_2 (C_S - C) \quad (7)$$

Eq.(7) is solved as follows:

$$\ln \left(\frac{C - C_S}{C_0 - C} \right) = - k_2 t \quad (8)$$

From Eq.(8), we can easily arrive at the reaeration coefficient k_2 , if there has been a change of concentration in the dissolved oxygen over a certain period of time as seen in the experiment, where C_0 represents the initial concentration of dissolved oxygen.

3.3 Consideration of k_2

The reaeration coefficient k_2 at each observation point was measured; concentration changes in the dissolved oxygen can be calculated from Eq.(8) as mentioned above. We examined first the effect on the reaeration by setting up the breakwater as follows: we isolated the effective region identifiable by its pronounced convex shape from the remaining spatial distribution of the dissolved oxygen as shown in Fig.9. We next calculated the value of k_2 for each section. Finally, we estimated the value of k_2 from the following procedure,

$$k_2 = \frac{\sum_i k_{2i} V_i}{\sum_i V_i} \quad (9)$$

where k_{2i} is i -th the value of k_2 and V_i is the volume of the i -th section.

Fig.10 shows the relationship between the reaeration coefficient k_2 and the wave steepness H/L . Generally, values of k_2 will only increase with the growth of the incident wave height because the wave length remains at a constant ($L = 75\text{cm}$) for all experiments. Furthermore, values of k_2 are seen to be larger as the breakwater width l becomes wider.

Consequently, the values of k_2 are in the range of $10^{-5} - 10^{-4}$ 1/sec. We have already decided on the equation to predict the reaeration coefficient by breaking waves on the uniform sloping bed (Hosoi et al., 1986). If we apply the equation to this experimental condition, we obtain values for k_2 approaching 10^{-3} 1/sec. This

logically implies that the effect of the slit-type breakwaters on aeration is about 1/10 less than that of the uniform slope bed.

Fig.10 Relationship between reaeration coefficient and incident wave steepness

Fig.11 Relationship between reaeration coefficient and dissipated energy

Fig.11 represents the relationship between the value of k_2 and the amount of the dissipated energy at the permeable wall. In this figure the dissipated energy is standardized by the amount of the incident energy of a wave measuring $H=1.5\text{cm}$, which is similar to one of the wave conditions already experienced. We can then deduce that aeration through the water surface near the breakwater depends on the energy dissipation caused by turbulence regardless of other factors such as the shape of the opening in the breakwater.

4. Conclusion

The characteristics of the diffusion and aeration near a permeable breakwater due to the wave action were discussed.

Results are summarized as follows.

- 1) The diffusion coefficients near the breakwater on the seaward and shoreward sides were estimated in the range of $10^{-1} - 7 \times 10 \text{cm}^2/\text{sec}$.
- 2) The mechanism of the water quality exchange through a permeable wall can be explained by using the concentration reflection ratio r .
- 3) The reaeration coefficients near the breakwater were estimated at values in the order of $10^{-5} - 10^{-4} 1/\text{sec}$. These values corresponded to a mean $1/10$ the value of the breaking wave on the uniform slope bed. Furthermore, the value of the reaeration coefficient increased with the increase of the incident wave height and wave energy dissipation caused by turbulence near the breakwater.

CHAPTER 12

Generalized Wave Theory for a Sloping Bed

D H Swart* and J B Crowley**

ABSTRACT This paper discusses the development from first principles of a first-order solution for non-breaking waves on a gently sloping bottom. The theory is derived in a similar fashion as was done by Swart and Loubser (1978) for vocoidal waves on a horizontal bottom. The resulting covocoidal theory was compared to an extensive data set for waves over a sloping bottom (Nelson, 1981) and is tested for analytical validity. It adheres exactly to continuity and the kinematic free surface boundary condition, and shows comparable errors in the dynamic free surface boundary condition to that found for the better, general horizontal bed wave theories.

1. BACKGROUND

In the past decade increasing emphasis has been placed in nearshore and coastal dynamics studies on the measurement in the field of wave and current motions, infragravity activity, suspended sediment loads and associated shoreline changes. These studies have demonstrated that periodic motions in the nearshore, non-breaking wave area are extremely non-linear. It has been shown that various time-independent wave properties such as the maximum horizontal orbital velocity at the bed and the transfer function between incident energy flux and longshore currents, are predicted reasonably well by using linear wave theory (e.g. Le Mehaute et al, 1968 and various recent references). However, time-dependent properties such as wave shape and orbital excursion are non-linear due to the shallow relative depth and asymmetrical due to the sloping bottom.

Elegant computer models are being developed to predict cross-shore wave-driven movement (Baillard, 1982, Stive, 1986). These models rely on an accurate prediction of wave-driven mass transport, and for this purpose use higher moments derived from orbital velocities predicted with Stokesian wave theories. Swart and Loubser (1979) already showed that this mass transport is a function of the non-adherence of these theories to the continuity

*Programme Manager, Coastal Processes and Management Advice, EMA, CSIR, Box 320, Stellenbosch, Republic of South Africa

**Coastal Processes and Management Advice, EMA, CSIR, Box 320, Stellenbosch, Republic of South Africa.

equation. In this respect the cross-shore transport theories would be improved by using a better higher-order wave theory, although this would admittedly increase the computational effort involved. Swart (1978) derived a variable-order cosinusoidal wave theory, the so-called vocoidal wave theory, from first principles. Swart and Loubser (1979) showed that as far as both experimental and analytical validity are concerned, vocoidal theory is comparable to the best other commonly used wave theories. Swart (1982) developed a higher-order Fourier analysis which allows the extraction of vocoidal component waves from a wave spectrum instead of sinusoidal or cosinusoidal waves as in a usual Fourier analysis. Swart (1987) reported on nearshore wave data, gathered in shallow water just outside the breaker zone. In as yet unreported analyses of the data, Swart found deviations from the observed spectra, which can be shown to be consistent with asymmetries associated with the waves shoaling on a sloping bed.

The purpose of the study reported on herein was therefore to investigate the possibility to generalise vocoidal theory to make it applicable for waves shoaling over mildly sloping bottoms. If this can be achieved, it would be possible to without excessive computer effort establish a technique to extract the non-symmetrical, higher-order wave shapes in shallow water and to predict orbital motions and higher moments thereof with greater accuracy than with the Stokesian theories. The potential to improve wave force calculations with asymmetrical waves would also be worth pursuing.

Section 2 reviews the method of derivation of the new theory, after which the analytical and experimental validity of the theory is reviewed in Sections 3 and 4. Section 5 contains a summary of conclusions.

2. DERIVATION

A very similar approach was followed for the development of the generalised vocoidal theory than was followed for the original derivation of vocoidal water wave theory on a horizontal bed. In the following the general assumptions, the governing equations, the boundary conditions and the derivation are given with regular reference to the horizontal bed derivation.

General assumptions

For the derivation of a generalised water wave theory the following general assumptions are made:

- * only non-breaking waves are considered;
- * the water movement is two-dimensional;
- * the flow is frictionless;
- * the fluid density is invariant in time and space,

- that is, the fluid is incompressible and homogeneous;
- * surface tension effects are neglected;
 - * the sea bed is mildly sloping, that is, it exhibits a slow variation in water depth in the direction of wave propagation;
 - * the wave motion is periodic and the slope is mild enough for relationship (1) below to be approximately valid.

$$\frac{d\theta(x,t)}{dt} = \frac{\partial\theta(x,t)}{\partial t} + c \frac{\partial\theta(x,t)}{\partial x} \quad \dots(1)$$

In expression (1) $\theta(x,t)$ is any time or space-dependent parameter, t denotes time, x is the distance in the direction of wave travel, and c denotes wave celerity. The second-last assumption above, namely, that of a mildly-sloping bed, implies in reality that it is assumed that the bed slope is mild enough to assume that the governing equations are not affected by the sloping bed. The only way in which the formulation used for the derivation of the theory is affected is via the boundary conditions at the sea bed which will be discussed in more detail below.

Governing equations

The three basic equations which govern the water wave problem are the equation for the conservation of fluid mass, the equations of motion and the expression for the rotationality of a fluid particle.

Continuity equation

In the case of an incompressible, homogeneous fluid in the two-dimensional situation, the continuity equation can be written as

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad \dots(2)$$

where z = vertical dimension positive upwards from the bed and u and w are velocity components in the x and z directions.

Equations of motion

For a frictionless fluid the two-dimensional equations of motion are:

x - direction:

$$\frac{1}{\rho} \frac{\partial \Phi}{\partial x} + \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} = 0 \quad \dots(3)$$

z - direction:

$$g + \frac{1}{\rho} \frac{\partial p}{\partial z} + \frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad \dots(4)$$

where p = pressure and ρ is fluid density.

Angular velocity

$$R = \frac{1}{2} \left(\frac{\partial w}{\partial x} - \frac{\partial u}{\partial z} \right) \quad \dots(5)$$

It should be noted that if equation (5) should point to a net rotation, this is purely the result of the mathematical manipulation. It can be used to derive rotational wave theories without considering how much such a type of flow i.e. frictionless, "rotational" flow could originate. It was shown, however, in e.g. the vortical theory (Swart 1978) that such an approach is advantageous in the development of the theory whilst the net rotation which results is in fact negligible (see Bleach, 1982).

Boundary conditions

The following three boundary conditions are used:

Kinematic bed boundary condition (KBBC)

$$w(x; z=0) = u(x; z=0) \tan \alpha \quad \dots(6)$$

(see Figure 1 for axis-notation)

Kinematic free-surface boundary condition (KFSBC):

$$w(x; z=d+\eta) - u(x; z=d+\eta) \frac{\partial \eta}{\partial x} = \frac{\partial \eta}{\partial t} \quad \dots(7)$$

where η = is the surface elevation, measured relative to the mean water level.

Dynamic free-surface boundary condition (DFSBC)

$$p(x; z=d+\eta) = 0 \quad \dots(8a)$$

Owing to the fact that the free surface is a streamline, one can use Bernoulli's equation for irrotational flow to transform equation (8) to:

$$Q = \frac{\eta}{d} + \frac{1}{2gd} \left[\{u(x; z=d+\eta) - c\}^2 + \{w(x; z=d+\eta)\}^2 \right] - \frac{c^2}{2gd} \quad \dots(8b)$$

where Q is the constant total energy along the free surface.

Further qualitative assumptions

Nelson (1981) specifically found that the various

parameters related to what could be termed bulk properties such as wave celerity and potential energy are virtually unaffected by the slope, whereas time - (or space -) dependent parameters are strongly affected. On the basis of the vocoidal horizontal bed solution and the various results obtained by Nelson (1981) specific, qualitative assumptions were made in addition to those already outlined above.

Swart (1979) assumed that the wave profile on a horizontal bed is qualitatively given by:

$$\frac{\eta}{H} = \text{voc}(P, X) - \eta_{*t} \quad \dots(9)$$

where $\text{voc}(P, X)$ = the vocoidal function = variable-order-cosinusoidal function

$$= \{\cos^2(\pi X)\}^P \quad \dots(10)$$

X = dimensionless time = t/T ; η_{*t} = dimensionless (with respect to wave height) trough depth and P is the wave profile parameter. The only assumption made regarding P is that it is equal to or greater than unity.

Analogously, it is assumed that the following qualitative definition is representative of **surface elevation** for a sloping bed:

$$\frac{\eta}{H} = h_\alpha \{\text{voc}(P, X) - \eta_{*t}\} + 0.5r_\alpha \{\text{cov}(P, X)(1 + \cos(\pi X)) - (1 - \eta_{*t})\} \quad \dots(11)$$

where $\text{cov}(P, X)$ is the newly defined "covocoidal" function given by

$$\text{cov}(P, X) = 1 - \text{voc}(P, X) \quad \dots(12)$$

and η_{*t} is defined in equation (9).

The parameters h_α and r_α are unknowns to be determined from the solution to the continuity equation, equations of motion and the surface and sea bed boundary conditions. It is assumed that P , the vocoidal wave profile parameter, has the same value as in the horizontal bed solution.

It can be seen that this equation for wave shape (equation 11) has the horizontal bed solution as a special case when $r_\alpha = 0$ and $h_\alpha = 1$.

The horizontal orbital velocity u is given by:

$$u/c = \frac{\eta}{H} \frac{M(X)k \cosh\{M(X)kz\}}{\sinh\{M(X)k(d+\eta)\}} + \frac{q_\alpha}{c(d+\eta)} \quad \dots(13)$$

where $M(X)$ is the vocoidal orbital velocity parameter and q_α is the mass flow due to a sloping sea bed. When $q_\alpha = 0$ this equation is the same as that used by Swart (1979) in the derivation of vocoidal theory.

It will be shown below that the effect of slope on the variation of $M(X)$ with X is such that the values of this parameter as obtained for a horizontal bed solution are not valid on a sloping bed.

It is assumed that the wave celerity c is defined by the same equation as for the horizontal bed vocoidal solution.

$$\frac{c^2}{gd} = \frac{1}{kd} \tanh(Nkd) \quad \dots(14)$$

This "assumption" was checked as part of finding a solution to the wave boundary value problem and was found to be valid as a first approximation (see Figure 2).

In solving for the wave boundary value problem as defined by equations (2) to (8b), the unknowns to be quantified are h_α and r_α (in equation 11) and $M(X)$ and q_α (in equation 13).

Solution for wave profile parameters r_α and h_α

The DFSBC is used to solve for the optimum ratio r_α/h_α . The rms value of the deviation over the wave profile ($0 < X < 1$) from the mean value of the Bernoulli constant Q (equation 8b) at the free surface, determines to what extent the theory adheres to the DFSBC, i.e.

$$E(\text{DFSBC}) = \frac{1}{4l} \left\{ \sum_{j=1}^{4l} (Q - \bar{Q})^2 \right\} \quad \dots(15)$$

where Q is given by equation 8b and \bar{Q} is the mean value of Q in the area $0 < X < 1$.

The value of q_α in the horizontal orbital velocity component is obtained from the continuity equation and the kinematic boundary conditions, namely,

$$\frac{q_\alpha}{c(d+\eta)} = \frac{\lambda}{d} \int_0^1 \left(\frac{u_s}{c} - \frac{u_b}{c} \right) \tan \alpha \, dX \quad \dots(16)$$

which also yields an expression for w , namely:

$$w = w(X) + w_{\text{mass}} + u \tan \alpha \quad \dots(17)$$

In the above subscripts "s" and "b" refer to "surface" and

"bed" respectively. In equation (17) $w(X)$ represents the cyclic vertical orbital velocity as given in the Appendix, with the qualification that the derivatives of η and $M(X)$ are derivatives of these values for waves on a slope. Furthermore w_{mass} is the component of the vertical orbital velocity which is due to the mass transport q_α . It can from the continuity equation be shown to be equal to

$$w_{\text{mass}} = \frac{q_\alpha}{d} \left(\frac{H}{\lambda}\right) (z/d) \frac{\partial(\eta/H)}{\partial X} (1+\eta/d)^{-2} \quad \dots(18)$$

The method of solution now involves finding that ratio of r_α/h_α for which the variation of $E(\text{DFSBC})$ is minimized. The following initial conditions were used:

$$T_c = 1, 2, 3, 4, 5, 10, 20, 30, 40, 50, 60.$$

$$H/d = 0.01, 0.02, 0.05, 0.10, 0.20, 0.50, 1.0.$$

$$\tan\alpha = 0.001, 0.002, 0.005, 0.01, 0.02, 0.05, 0.10, 0.20.$$

The numerical results for r_α/h_α were shown by inspection to be functions of H/d , T_c and $\tan\alpha$.

$$r_\alpha/h_\alpha = G(H/d, T_c, H/d) \quad \dots(19)$$

The detailed curve-fitted expressions for r_α/h_α are given in Table I.

The absolute values of r_α and h_α are determined by the fact that

$$\eta_c - \eta_t = H \quad \dots(20)$$

where subscripts c and t refer to "crest" and "trough" respectively. η_c and η_t are known in terms of r_α and h_α . Tables IIa and IIb show typical values of r_α and h_α .

Solution for orbital velocity parameters $M(X)$ and q_α

The orbital velocity parameter $M(X)$ is found by rewriting the particle rotation R (equation 5) through substitution of the appropriate expressions for u and w . In the same way as was done by Swart (1979) the orbital velocity parameter was found by defining

$$M(X) = R_M M_1(X) \quad \dots(21)$$

where $M_1(X)$ is the first-order, i.e. small amplitude, approximation of $M(X)$ and R_M is the correction which has

to be made to negate the small-amplitude assumption. It is assumed that the expression for R_M in the Appendix is also valid for the covocoidal theory. The value of $M_1(X)$ is found from the small-amplitude, covocoidal version of equation 5, that is

$$\frac{\partial^2(\eta/H)}{\partial X^2} + 4\pi^2(\eta/H) M_1^2(X) = 0 \quad \dots(22)$$

It can be shown (Swart, 1988) that at the wave crest ($X=0$) the values of M_1 for covocoidal and vocoidal theory are related, namely

$$M_{1c}(\text{covoc}) = (h_\alpha - r_\alpha)^{0.5} M_{1c}(\text{voc}) \quad \dots(23)$$

$M_1(\text{covoc})$ is called $M_{c1\alpha}$ herein.

Swart (1988) solved for $M_1(X)$ from equation (22) for a range of initial conditions, namely

$$\begin{aligned} T_C &= 1, 2, 3, 4, 5, 10, 20, 30, 40, 50, 60 \\ h/d &= 0, 01, 0.02, 0.05, 0.10, 0.2, 0.5, 1.0 \\ r_\alpha/h_\alpha &= 0.01, 0.02, 0.05, 0.10, 0.20, 0.40 \end{aligned}$$

Figure 3 shows a typical variation of $M_1(X)$ for covocoidal theory in comparison with $M_1(X)$ for vocoidal theory on a horizontal bed. The value of $M_1(X)$ at $x = 0.5$ was called $M_{t1\alpha}$ and was established from the numerical results for the whole range of initial conditions to be

$$M_{t1\alpha} = g_1(T_C) g_2(r_\alpha/h_\alpha) \quad \dots(24)$$

Curve-fitted expressions $M_{t1\alpha}$ given in Table III.

It is straightforward to find a solution for q_α . Equation (16) was integrated numerically using the Rombert integration method for a range of initial conditions:

$$\begin{aligned} T_C &= 5, 10, 20, 30, 40, 50, 60 \\ H/d &= 0.1, 0.2, 0.5, 1.0 \\ \tan\alpha &= 0.01, 0.02, 0.05, 0.10 \end{aligned}$$

By means of curve-fitting an expression was found from the numerical results for the mass transport velocity:

$$\frac{q_\alpha}{c(d+\eta)} = R(H/d, T_C, \tan\alpha) \quad \dots(25)$$

The nature of the function R is given in Table IV.

This concludes the derivation of covocoidal theory.

3. ANALYTICAL VALIDITY

As part of the validation of vocoidal water wave theory for a horizontal bed Swart and Loubser (1979) performed an analytical validity study in which the adherence of vocoidal theory to the original governing equations and boundary conditions was compared with that for twelve other commonly used water wave theories, namely, linear Airy theory, Stokes II and V, three different gravity cnoidal theories, Dean's stream function theory, two different rotational cnoidal theories and three different approximated wave theories. The two free surface boundary conditions and the adherence to the continuity equation were computed for each of the theories for a wide range of initial conditions.

Vocoidal theory adheres exactly to the kinematic free surface boundary condition and the continuity equation. Swart and Loubser (1979) showed that the error in the DFSBC was for a range of non-linearities covering all non-breaking waves either the lowest of all theories tested or not statistically different from the theory with the lowest error at the 95 per cent confidence level, for non-linearity values exceeding 260, which cover intermediate and shallow water conditions.

In exactly the same manner as was done in the Swart and Loubser study the error in the DFSBC was computed at 41 equidistant points over one wave period for covocoidal theory and a mean error calculated in subsets which were chosen to represent waves of roughly equal non-linearity, i.e. which had approximately equal wave shapes. The results were compared with those for vocoidal theory in the earlier study and it was concluded that although covocoidal theory exhibits errors in the DFSBC which grow marginally bigger as slope increases (see Figure 4), the covocoidal theory still had such small errors in the DFSBC that it did not differ significantly at the 95 per cent confidence level from vocoidal theory, which as stated above was shown to be amongst the best theories in the Swart and Loubser (1979) study as far as adherence to the DFSBC is concerned (see Figure 4). It is therefore concluded that the theory has a sufficiently sound basis to serve as a good first approximation of waves on a sloping bed.

4. EXPERIMENTAL VALIDITY

Experimental validation studies for wave theories have traditionally used laboratory data (Le Mehaute *et al*, 1968; Swart and Loubser, 1979 and Hattori 1986). Good full-scale data are nowadays being gathered in the field and in mega-flumes. Due to the fact that such data are usually for random waves, it is not simple to establish

the exact cause(s) of correspondence or non-correspondences of theory to data.

Nelson (1981) performed an extensive set of experiments for slopes from horizontal to 1 in 10, to test the effect of bed slope on wave profile parameters and wave celerity. His celerity data yield results totally compatible with the theoretical predictions in Figure 2. Figure 5 defines the wave profile parameters tested. Using the same range of initial conditions (H/d , T_c , $\tan\alpha$) as in the Nelson study, theoretical predictions of the parameters defined in Figure 5 were made. The resulting correspondences between Nelson's measured data and the theoretical predictions in this study are shown in Figure 6. It can be concluded that good, qualitative correspondence is achieved, although there are some quantitative divergences. Nevertheless, wave shape changes on beds of different slope are predicted well as a first approximation.

Swart and Loubser (1979) showed that vocoidal theory was consistently the best predictor of the thirteen theories tested as far as the prediction of horizontal orbital velocity is concerned. No good data exists to test systematically the effect of increasing bottom slope on the orbital velocity. Four orbital velocity data sets were selected from the Swart and Loubser study which have roughly similar initial wave conditions (H/d , T_c) and for which the bed slope varies between 0 and 1 in 20. Although the covocoidal orbital velocity shows some improvement over vocoidal theory, particularly as far as the variation of orbital velocity under the wave trough with distance from the bed is concerned, the improvement expected in the absolute value of the orbital velocity did not materialise (see Figure 7). Nevertheless, the overall correspondence with the data is satisfactory. To improve the inconclusiveness as far as orbital velocity prediction is concerned, emphasis should be placed on gathering high quality orbital velocity data, preferably in the field to eliminate the introduction of spurious mass transport, for a range of bed slopes.

5. CONCLUSIONS

- A new wave theory, the so-called covocoidal wave theory, was derived from first principles and is valid for all non-breaking waves on a mildly sloping bottom.
- No simplifying assumptions were made and the finite amplitude condition was preserved. Some approximation was, however, introduced because the numerical results were represented by means of curve-fitted expressions to facilitate easier application.

- The **analytical validity** of the theory was established to be as good as or better than the better, commonly-used horizontal bed wave theories, by virtue of the fact that the theory adheres exactly to the KFSBC and to continuity and has a minimised error in the DFSBC which was shown to not differ statistically from vocoidal theory (for $\tan\alpha=0$) at the 95 per cent confidence level.
- **Experimental validity** was established primarily by comparison of theoretical predictions with an extensive data set collected by Nelson (1981) to establish the effect of bottom slope on wave profile parameters and wave celerity. Indications on the prediction of orbital velocity are inconclusive due to the lack of appropriate data.
- The new **covocoidal theory** can serve as basis for the study of a variety of wave processes on a sloping bed outside the breaker zone.

CHAPTER 13

Wave Groups on Wave Records Measured Along Spanish Shores

Adolfo Marón *

Abstract

A large amount of wave records measured at four different locations of the Spanish shores have been analysed from the point of view of wave group formation. The influence of wave climate and depth on the results is studied. The results are compared with existing theories for runs of waves, SIWEH and envelope functions. Characteristics of extreme groups are also considered

1 Introduction

It is generally recognized the importance that the presence of wave groups can have in the behaviour of coastal and offshore structures and consequently many studies have been carried out trying to determine the grouping characteristics of ocean waves.

As a consequence of these studies, different theories have been proposed to explain the formation of groups among wind generated waves. These theories try to relate the groupiness characteristics observed in the waves with other better known wave properties (spectral parameters, zero crossing statistics and others).

All of them could be divided into two main groups: those which defend that the formation of groups can be explained by pure linear interactions and those which propose the contrary. No definitive conclusion has been reached yet (Marón, 1986).

Among the linear methods we have selected those corresponding to the statistics of runs of high waves (Goda, 1976 and Kimura, 1980), the SIWEH function (Funke & Mansard, 1980) and the envelope theory (Longuet-Higgins, 1984) as well as different modifications introduced by several authors. Most of the studies have deal with simulated records and only a few have analysed measured records and generally not in a systematic basis.

For this study we have implemented a computer program which calculates all the parameters for wave groupiness proposed in the previously mentioned works as well as others relating to extreme events which we think that can be of

(*) Programa de Clima Marítimo y Banco de Datos Oceanográficos. P^a de la Castellana n^o 16 - 5^a Dcha. 28046 Madrid Spain. Tel: 34.1.431 28 99

interest in design. This program was run on a large amount of wave records measured in four different locations of the Spanish shores by means of moored waverider buoys.

We intended in this way to evaluate the ability of the different theories to predict the observed results. At the same time we tried to see if the groupiness characteristics were affected directly by local maritime climate factors or in the contrary they only depend on spectral and/or statistical wave properties independently of site.

Finally, one of the buoys was moored in relatively shallow waters and therefore it can give us some indication on how shoaling could affect the group behaviour.

2 Description of wave data

The main characteristics of the four buoys used in the analysis are presented in Table I.

TABLE I
MAIN BUOY CHARACTERISTICS

Buoy	Net	Sea	Depth	No. of points	No. of records
BILBAO	REMRO	Cantabric	50	5120	2605
CARTAGEMA	REMRO	Mediterranean	70	5120	4420
SEVILLA-3	Special	Gulf of Cadiz	10	*	613
SEVILLA-4	Special	Gulf of Cádiz	38	*	1327

* Variable for each record between 675 to 1500.

Fig. 1.- Buoy locations

Their locations can be seen in figure 1. Two of the buoys belong to the REMRO Net (Spanish Net for Wave Recording and Measurement) owned by the Spanish Port and Shore Authority. The other two buoys were deployed by the Sevilla Harbour Authority for a special campaign. The records from the first two buoys are specially adequate for group analysis because of their long length of 5120 points at a sampling rate of 2 Hz.

Regretfully the other two sets of records are of very short and variable length which increases the variance and the uncertainty in the results. Although they are not the best buoys for group analysis, they were the only available

case of two buoys in different depths but at very near positions.

The BILBAO buoy is located in a place characterized by strong storms and frequent presence of long swell coming from the North Atlantic. The CARTAGENA buoy is located in the Mediterranean Sea and therefore the waves are shorter and steeper than in the previous one, also the possibilities of swell are very reduced. The two SEVILLA buoys are moored in the Atlantic Ocean but due to their positions, they are protected from most of the swell and bigger storms.

A quality control program has been applied to all the records in the study. Any record considered incorrect or suspected to be so was rejected for the analysis. A correction to allow for the transfer function of the buoy electronics was applied to the records. This transfer function affects mainly the phases of the Fourier components of the wave record and therefore it can have a great influence in the results as far as groupiness is concerned.

3 Statistics of runs of high waves

The length of a run of high waves (R) is the number of consecutive waves that are higher than a given threshold. The corresponding length of group (L) is the number of consecutive waves from the beginning of a run to the beginning of the next one. The wave height is defined by the zero upcrossing method rejecting waves lower than 10% of the standard deviation or shorter than one second.

Goda (1976), assuming no correlation between consecutive wave heights, proposed the following distributions for R and L:

$$R(i) = Pr(R = i) = P_0^{i-1} Q_0 \quad L(i) = Pr(L = i) = \frac{P_0 Q_0}{P_0 - Q_0} (P_0^{i-1} - Q_0^{i-1})$$

where P_0 and Q_0 are the exceedence and nonexceedence probabilities for the given threshold. As a consequence the respective mean values are given by:

$$R = \frac{1}{Q_0} \quad L = \frac{1}{P_0} + \frac{1}{Q_0}$$

The exceedence probabilities can be estimated theoretically by assuming a Rayleigh distribution for the wave heights.

As an example, figure 2 compares these theoretical results with the measured mean distributions for R and L for the threshold at the mean wave height and for records with wave height correlations below 0.1 and between 0.4 and 0.5. Here and in the following the curves give the theoretical values, the solid dots are the results for BILBAO, the open

dots the results for CARTAGENA, the solid squares are those of SEVILLA-3 and the open squares those of SEVILLA-4.

Mean distribution of runs & groups for hmean

Fig.2.- Mean distributions of group and run length, compared with Goda's theory.

It can be seen that the theory is quite good for records with low or no correlations but the lengths are underpredicted for records with high correlations, results which are coincident with those from other authors. The comparisons when other thresholds are considered are very similar.

It should be kept in mind that these and the following results are in general accompanied by a big dispersion about the mean, specially for the shorter records of the SEVILLA buoys, but these dispersions are not considered in this study for simplicity.

Fig.3.- Probability of exceedence as a function of wave height correlation, compared with Rayleigh distribution.

The differences with the theory for records with high correlations could be due to the simplifying assumptions but also to the fact observed in the records that the Rayleigh distribution is not completely correct when the correlation be-

tween successive wave heights is high. In figure 3, it can be seen that the exceedence probabilities are overpredicted for the mean height and underpredicted for the significant wave height at high correlation values.

Fig.4. Mean run and group length.

Anyway, figure 4 indicates that the errors in Goda's formulation can not be explained by this feature because the results are far from the theory even when the probabilities estimated from the records are used. This is specially true for the BILBAO and CARTAGENA buoys which happens to be the ones measuring higher correlations.

Kimura (1980) introduced the correlation between successive wave heights in the formulation, resulting in the following equations:

$$R(i) = (1 - P_{22})P_{22}^{i-1} \qquad L(i) = (1 - P_{11})(1 - P_{22}) \frac{P_{11}^{i-1} - P_{22}^{i-1}}{P_{11} - P_{22}}$$

Here the probabilities P11 and P22 are defined as:

$$P_{11} = Pr(H_i \leq H_0 | H_{i-1} \leq H_0) \qquad P_{22} = Pr(H_i > H_0 | H_{i-1} > H_0)$$

and H_0 is the threshold considered. These probabilities can be calculated assuming a two dimensional Rayleigh distribution for the joint distribution of successive wave heights. This distribution depends on a shape parameter k which can be related to the statistical or spectral properties of the records in different ways. In this study three different formulations have been investigated: Uhlenbeck (1943) equation relating the correlation between successive wave heights and the shape parameter, Longuet-Higgins (1984) relation between k and the spectral shape and Battjes (1983) equation based in the correlation between the squares of the wave heights. The comparisons between them have shown some superiority for the first approach in predicting the results although the differences are not very important. In the following the first equation is used.

Figures 5 and 6 compare Kimura's theory with the measurements for two different thresholds. Here two theoretical curves are plotted for each distribution, corresponding to the lower and upper bound of the

correlation. The agreement is very good except for the SEVILLA's buoys at high correlation but this is due to the fact that only a small number of records has been found with this correlation values and therefore the statistical variability is very high.

Mean distribution of runs & groups for hmean

Fig.5.- Mean distributions of group and run length for Hmean, compared with Kimura's theory. Upper plot is for high correlation and lower plot is for low correlation values.

Mean distribution of runs & groups for hm0

Fig.6.- Same as figure 5 but for Hm0.

The mean run and group length can be calculated from the given distributions:

$$\bar{R} = \frac{1}{1 - P_{22}}$$

$$L = \frac{1}{1 - P_{11}} + \frac{1}{1 - P_{22}}$$

Fig.7.- Mean run length compared with Kimura's theory. Upper curve is for H_{m0} and lower if for H_{mean} .

These are compared with the results in figures 7 and 8. The agreement is very good except for a small overprediction of the mean group length at the significant level. This could be due to an overprediction of P_{11} at this level. The error is in any case below 10%.

Fig.8.- Mean group length compared with Kimura's theory. Lower curve is for H_{mean} and upper is for H_{m0} .

Ewing (1973) gave another formulation for the mean run length based in the envelope theory and whose main result can be written as:

$$\bar{R} = \sqrt{\frac{m_2}{2\pi\mu_2}} \frac{2\sqrt{m_0}}{H_0}$$

where the m_i are the spectral moments of order i , μ_2 is the second order central moment of the spectrum and H_0 is the threshold level. Here the length of run is counted in a continuous basis and should be corrected for discrete counting in order to be comparable with the zero crossing measurements. This can be done by using the following relationship:

$$\bar{R} = \frac{1}{1 - \exp(-\frac{1}{\bar{R}})}$$

From the previous equation an asymptotic expression valid for narrow banded spectra can be found:

$$\bar{R} = Q_p \sqrt{\frac{2m_0}{H_0}}$$

$$Q_p = \frac{2}{m_0^2} \int_0^\infty f S(f)^2 df$$

Where Q_p is the peakedness parameter proposed by Goda.

Fig. 9.- Comparison with Ewing's equation

Fig. 10.- Ewing's parameter vs. correlation.

Fig. 11.- As figure 9 but for filtered records.

Figure 9 gives the measured values plotted against the first factor of Ewing's equation. The results compare very bad with the theory and are quite different for each buoy. This can be explained by the fact that the parameter considered is uncorrelated with the wave height correlation as can be seen in figure 10. Another evidence of this is that if one computes this factor for a Jonswap spectrum the result is independent of the peak enhancement factor while it is clear that more peaked spectra give longer runs.

If one filters the records (see the envelope section later in the paper) the correlation between the measurements and Ewing's factor is much better but still far from the theory (figure 11).

Fig.12.- Comparison with Ewing's asymptotic equation.

Fig.13.- Relationship between Q_p and correlation.

This is specially so for the BILBAO and CARTAGENA buoys which are the more reliable ones. The relation for these two buoys can be approximated by:

$$y = 0.28 \ln Q_p + 0.10$$

4 Analysis of SIWEH function

Funke & Mansard (1980) proposed the SIWEH function (Smoothed Instantaneous Wave Energy History) as a mean to recognize the presence of groups in the wave records. This function is obtained by convoluting the square of the signal with a triangular window of a width equal to the spectral peak period. In the present study the convolution is actually made in the frequency domain.

The same authors have proposed two parameters obtained from the SIWEH in order to characterize the group formation.

The asymptotic equation gives acceptable results only for high values of Q_p (figure 12). Here the Q_p calculated from the raw spectra have been corrected to account for the bias in the estimator (dividing by 2). It seems from the results that Ewing's theory will only be valid for spectra narrower than those found in nature.

Anyway, the peakedness parameter is a good indicator of groupiness as can be deduced from figure 13, where a good relationship is observed between it and the wave height correlation.

They are the groupiness factor and the mean SIWEH period which are given by:

$$GF = \frac{1}{m_0} \sqrt{\frac{1}{T_0} \int_0^{T_0} [E(t) - \bar{E}]^2 dt}$$

$$T_{SIWEH} = \frac{1}{T_p} \frac{1}{N_0} \sum_{i=1}^{N_0} T_{Si}$$

where $E(t)$ is the SIWEH function, \bar{E} its mean value, t_0 is the length of the records, T_p is the spectral peak period, N_0 is the number of zero upcrossings of the SIWEH and T_{Si} are the corresponding zero upcrossing periods.

Fig.14.- SIWEH period/groupiness factor.

Figure 14 presents the observed relation between these two parameters. The result is the same for the four buoys and can be approximated by the straight line:

$$T_{SIWEH} = 3.92GF + 2.55$$

Fig.15.- SIWEH period/correlation.

Also the mean period of the SIWEH is related to the wave height correlation (figure 15) in a similar way for the four buoys which can be approximated by:

$$T_{SIWEH} = 8.7\gamma^2 - 0.45\gamma + 4.3$$

Fig.16.- Groupiness factor/correlation.

On the contrary, figure 16 indicates that the relationship between the groupiness factor and the correlation varies with the buoy considered. This relation approximates straight lines with the same slope but different inter-

Fig.17.- SIWEH period/mean group Length.

Figure 17 indicates that a linear relation exists between these two quantities but again it depends on the buoy considered. The two SEVILLA buoys behave exactly in the same way and the same happens with BILBAO and CARTAGENA buoys.

5 The envelope function

The envelope of all the records has been computed by using the complex pre-envelope function. Following a recommendation by Longuet-Higgins (1978) the same has been made for filtered records obtained by suppressing all the frequencies in the raw signal below .5 the spectral peak frequency and above 1.5 the same frequency.

In the first place we looked at the effect of this filtering in the characteristics of the signal and we observed that while the total variance is only slightly reduced and other spectral and statistical parameters are not significantly changed, the spectral width suffers a drastic change.

Fig.18.- Comparison between the bandwidth after and before filtering.

cepts for each buoy. Only the two SEVILLA buoys present a similar behaviour.

The mean SIWEH period is an indication of the length of group and therefore should be related to the mean length of groups obtained in the previous paragraph.

This will result in completely different group behaviours as predicted by the envelope theory. In figure 18 the bandwidth (measured by ν , defined later) after filtering is compared with the raw record value.

Both bandwidths are uncorrelated or even negatively correlated for the BILBAO buoy.

A level crossing analysis of the envelope has been performed at different levels. From it a mean run and group length can be computed. The theory predicts their values as given by:

$$\bar{R} = \frac{1}{\sqrt{2\pi}} \sqrt{\frac{1+\nu^2}{\nu}} \frac{2\sqrt{m_0}}{H_0} \quad \bar{L} = \frac{1}{\sqrt{2\pi}} \sqrt{\frac{1+\nu^2}{\nu}} \frac{2\sqrt{m_0}}{H_0} \exp\left(\frac{H_0^2}{8m_0}\right)$$

Here H_0 is two times the level considered and ν is a measure of the spectral bandwidth given by:

Fig.19.- Envelope results for raw records.

$$\nu = \sqrt{\frac{m_2 m_0}{m_1^2} - 1}$$

The results obtained for the raw and filtered records can be seen in figures 19 and 20. The continuous lines correspond to the level which is near the mean height and the dashed lines are for which is the significant height. The measurements agree very well with the theory except maybe in some cases for the SEVILLA buoys but this could be most probably due to the statistical variability. Only the mean group length at the significant level seems to be overestimated by the theory for this two buoys.

Fig.20.- Envelope results for filtered records.

A comparison of the results obtained with this procedure and those corresponding to the zero crossing

analysis was made. It was found that no relation is apparent between both results when the raw records are considered but

some correspondence is found if the filtered record envelopes are considered (figure 21) although it depends on the buoy selected. This fact seems to support the need of the filtering for the envelope analysis.

Fig.21.- Envelope/zero-crossing run length.

6 Longest group and run

Assuming that the kimura's distribution is correct, one can easily compute the theoretical distribution of the longest run and group in a record. These will be dependent on the number of runs present in the record and therefore on the mean group length and mean wave period for records of a fixed length.

Fig.22.- Longest group and run for Hmean and Hm \emptyset and different correlations.

From these distributions the expected values can be estimated. Figure 22 presents the results obtained for the means of the longest run and group adimensionalized by the respective means compared with the values predicted by the theory. Two threshold levels have been considered. The theoretical values have been numerically approximated on the computer because no closed form was found for the resulting expressions. As the distribution depends on the wave correlation, the records have been grouped into classes of correlation and two cases are presented in the figure representative of low and high correlations. The two theoretical curves correspond to the lower and higher values of each class.

The agreement with the theory is quite good although the observed scattering is somewhat higher than in the previous results, but this is always to be expected when dealing with extreme order statistics.

7 Conclusions

- * The theory developed by kimura predicts very well the group behaviour of waves. The correlation between successive wave heights seems to be the best indicator of groupiness. Some discrepancies are found between the observations and the Rayleigh distribution for wave heights.
- * The formalations proposed by Ewing are not correct for the range of values observed in nature.
- * The groupiness factor and mean period of the SIWEH are good indicators of group characteristics but the results depend in some cases on the buoy considered and this is probably due to differences in the wave correlations at the different sites. Therefore, it seems that some information on groupiness is lost with these parameters.
- * The envelope theory performs quite well. A previous filtering of the signal seems to be needed in order to get results coherent with other analysis methods.
- * No significant difference was found between the buoys that could not be explained by differences in the correlation and therefore it can be concluded that the group formation is independent of the local maritime climate and depth variation for the depths considered here.

CHAPTER 14

Are solitary waves the limiting waves in long wave runup ?

Costas Emmanuel Synolakis †, A.M., ASCE

This is a study of the maximum runup of single long waves on plane beaches. Laboratory data are presented that suggest that solitary waves attain the higher runup distances than other single long waves with identical generation characteristics, such as energy or momentum. These results suggest that solitary waves may provide a limiting condition for long wave runup on plane beaches.

1. Introduction.

The problem of determining the runup and reflection of long single waves usually arises in the study of the coastal effects of tsunamis. Tsunamis are long water waves of small steepness generated by impulsive geophysical events on the ocean floor or at the coastline. Solitary waves and cnoidal waves are believed to model important aspects of the coastal effects of tsunamis well and in the past twenty years there has been a large number of analytical, numerical and laboratory investigations studying the runup of solitary waves. There has been comparatively less attention paid to the runup of cnoidal waves. However, consensus has emerged that one suitable physical model for this process is the formalism of a long wave propagating over constant depth and encountering a sloping beach.

A comprehensive review of these results may be found in Synolakis (1986, 1987, 1988), where some basic questions—such as the analytical substantiation of empirical relationships—have been resolved. However a basic question still persists and it refers to the actual shape of tsunamis in nature which are rarely Boussinesq-solitary wave-like or cnoidal wave like. Therefore most analytical results have only been used to calibrate numerical codes which solve the equations of motion with more “realistic” and “tsunami-like” profiles and actual topographies.

Unfortunately there is little knowledge as to what constitutes a “realistic” tsunami profile for specifying boundary or initial conditions in numerical solutions. No data exist on the surface elevation of a tsunami at generation and little data exist on the elevation of tsunamis far from the source, although this is likely to change with the field implementation of the THRUSH program (Bernard, 1988).

† Assistant Professor, School of Engineering, University of Southern California, Los Angeles, California 90089-0242

The question then arises of whether it is useful to develop numerical schemes correct to many orders of approximation when realistic initial or boundary data do not exist. One could argue that the details of the wave at generation may not be very important in the eventual propagation process and the coastal effects; it is well established that long waves fission after sufficient propagation distances into series of solitary waves. However, then the process can be described relatively well analytically.

In this paper, I will report some preliminary data that address this question in particular. I will describe a series of laboratory experiments which suggest that although the details of the wave at generation are important in estimating the coastal effects at finite distances, it is possible to use solitary wave theory to obtain a limiting condition for long wave runup.

2. Basic phenomenology and dimensional analysis.

Consider the two-dimensional topography consisting of a constant depth region of depth d encountering a plane sloping beach of angle β . This is the model most frequently used in calibrating numerical codes and it is only appropriate to check its sensitivity to different initial conditions. The topography is shown in figure 1.

Figure 1. A definition sketch for long wave runup.

Waves will be generated with a vertical plate moving horizontally along the path $x = \xi(t)$, $0 < t < T$, and where T is the generation time. The origin of the coordinate system is at the initial position of the wavemaker and x increases seaward. The problem can be stated as finding the maximum runup R that a wave motion generated with trajectory $\xi(t)$ at a distance L from the generator in a fluid of depth d , density ρ and viscosity μ will attain on a sloping beach of angle β . It is

assumed that the flow boundary is hydrodynamically smooth. The following table lists the independent and dependent variables. The appropriate units are included in parentheses.

DIMENSIONAL ANALYSIS †

R	is the maximum runup	(L),
d	is the depth of the constant depth region,	(L),
T	is the characteristic generation time	(T),
S	is the stroke of the generator	(L),
L	is the propagation distance	(L),
β	is the angle of the sloping beach	(-),
g	is the acceleration of gravity	(L/T^2),
ρ	is the density of the fluid	(M/L^3),
and		
μ	is the viscosity of the fluid	(M/LT).

In dimensional terms, one can write

$$\mathbf{R} = \mathcal{F}(d, \mathbf{S}, \mathbf{T}, \rho, \mu, L, g, \beta). \quad (1)$$

If the equations of motion were solvable for arbitrary plate trajectories, specification of the independent variables on the right hand side of equation (1) would be sufficient to define the runup exactly. Unfortunately, no analytical or numerical methods exist to calculate the evolution of a wave through breaking to its maximum runup and it is necessary to conduct laboratory experiments to determine the functional form of \mathcal{F} .

Buckingham's π -theorem suggests that six independent groups can be constructed. The following is one possible grouping of variables ‡,

$$\frac{\mathbf{R}}{d} = \mathcal{F}\left(\beta, \frac{(\mathbf{S}/\mathbf{T})d}{\mu/\rho}, \frac{\mathbf{S}}{\mathbf{T}\sqrt{gd}}, \mathbf{T}\sqrt{\frac{g}{d}}, \frac{L}{d}\right). \quad (2)$$

† In this list, I have replaced the trajectory time history $\xi(t)$ with the maximum stroke \mathbf{S} and the generation time \mathbf{T} . During the experiments, $\xi(t)$ will be varied and \mathbf{S} and \mathbf{T} will be kept constant to determine the effect of the details of the trajectory.

‡ As is customary, the variable have been assembled in dimensionless groups that have the form of standard fluid mechanics parameters such as the Reynolds number $Re = (\mathbf{S}/\mathbf{T})d/(\mu/\rho)$ and the Froude number $Fr = \mathbf{S}/(\mathbf{T}\sqrt{gd})$.

For fixed propagation distances L , inviscid flow $\mu = 0$, and fixed slopes β , this list reduces to †

$$\frac{\mathbf{R}}{d} = \mathcal{F} \left(\frac{\mathbf{S}}{\mathbf{T}\sqrt{gd}}, \mathbf{T}\sqrt{\frac{g}{d}} \right). \quad (3)$$

One can now speculate on the possible form of the function \mathcal{F} . For a given depth, and given generation number $Fr = \mathbf{S}/(\mathbf{T}\sqrt{gd})$, as the generation time $\mathbf{T}\sqrt{g/d}$ increases the normalized runup \mathbf{R}/d should increase, because then the stroke increases in proportion and higher waves are generated. However, this increase should not be observed for very large generation times because then the waves become unstable, break at generation and fission to smaller waves. It is likely that for each given value of the generation number, there exists some limiting generation time beyond which no further increases in runup would be possible. This would imply runup saturation and it would provide a limiting condition for long wave runup.

Whether this speculation is correct and whether different $\xi_1(t) \dots \xi_n(t)$ with identical $\mathbf{S}/(\mathbf{T}\sqrt{gd})$ and $\mathbf{T}\sqrt{g/d}$ result in different \mathbf{R}/d is unknown and will be explored in the next sections.

3. Experimental results.

Experiments were conducted in the 40m wave tank facility of the W.M. Keck laboratories of the California Institute of Technology. The facility is equipped with a programmable hydraulic wave generator and a wave measuring system. A ramp of slope 1 : 19.85 was installed at one end of the tank to model a uniformly sloping beach. The ramp surface was made of anodized aluminum panels and it was hydrodynamically smooth over the range of flows studied.

The experimental procedure is described in detail elsewhere (Synolakis, 1986, 1987). The experiments consisted of specifying a normalized plate trajectory shape $\xi(t)/d$ and of then varying \mathbf{S} and \mathbf{T} and of measuring \mathbf{R} until a sufficiently large data set was generated to draw some preliminary conclusions.

3.1 Ramp trajectory. Type R waves.

The simplest possible plate motion is a ramp trajectory defined by

$$\begin{aligned} \xi(t) &= \left(\frac{\mathbf{S}}{\mathbf{T}}\right)t, \quad 0 < t < \mathbf{T}, \\ \xi(t) &= 0, \quad t > \mathbf{T}. \end{aligned} \quad (4)$$

† I have resisted the temptation to use an Irribaren like parameter in this analysis. This type of long waves change substantially as they propagate over constant depth and it is difficult to define the wave steepness consistently. If further analysis is desired, a tabulation of the data may be found in Synolakis (1986).

Figure 2 The wave hierarchy generated with a ramp trajectory with generation time $T\sqrt{g/d} = 7.2$ and different strokes. The profiles were measured at approximately 20 depths away from the wave generator. The profiles are not synchronized in time and their relative positions do not necessarily reflect differences in propagation speeds.

In this case the entire wave generation process is described by three parameters only, the depth, the stroke and the generation time. For identification purposes in the subsequent discussion, these waves will be referred to as type R waves.

The experiments covered a range of depths from 12.60 to 20.24cm, a range of dimensionless times $T\sqrt{g/d}$ from 3.481 to 15.747 and a range of generation numbers $S/(T\sqrt{gd})$ from 0.034 to 0.846. Small generation numbers ($S/(T\sqrt{gd}) < 0.11$) resulted in waves that never broke and in small runup heights ($R/d < 0.22$) larger generation numbers ($S/(T\sqrt{gd}) < 0.37$) resulted in waves that broke as they climbed up the beach and in larger runup heights ($R/d < 0.80$). Larger numbers ($Fr < 0.65$) produced waves that broke before reaching the beach, reformed and then broke again as they climbed up the beach. Relatively large generation numbers ($Fr < 0.84$) produced waves that were generated broken and propagated broken without ever reforming. These waves were essentially bores of finite volume and they had the highest runup distances $R/d \approx 1$. Further increases in the generation number did not result in larger runup; there was runup saturation.

Figure 2 presents the surface elevation time history of one series of such waves generated with similar generation times but with generation numbers differing by an order of magnitude. All waves shown assume the shape of a leading solitary wave followed by an oscillatory tail. The second hump seen at about 100 dimensionless time units behind the leading wave is the reflected wave generated by the beach.

The relationship of the runup of the waves generated with a ramp motion (4) with the generation number is presented in figure 3. All the wave shown are waves that broke only as they climbed up the slope. As expected, the relative runup increases with the generation number. Also as anticipated, for fixed generation numbers, the relative runup increases with the generation time.

3.2 Solitary wave-like trajectory. Type S waves.

In this set of experiments waves were generated using different solitary wave-like trajectories. A solitary wave trajectory is a plate motion that produces a solitary wave of given H/d at a given depth d . This trajectory is the solution of the equation

$$\xi(t) = \frac{H}{kd} \tanh k(ct - \xi(t)), \quad (5)$$

where $k = \sqrt{(3/4)H/d^3}$ and $c = \sqrt{g(H+d)}$ (Goring, 1978).

The correct stroke and generation times for solitary waves are $S = \sqrt{(16/3)Hd}$ and $T = (2/kc)(3.80 + H/d)$. † If different values are specified, then the generator

† It has been verified *ibid* and in Synolakis (1986, 1987) that these values produce true Boussinesq solitary waves $\forall 0.08 < H/d < 0.68$. However, depending on the response of the generation system fine tuning may be necessary to obtain perfectly clean waves. Specifically, T may have to be adjusted by 5%.

Figure 3 The variation of the normalized runup with the generation number. Type R waves. All waves shown break only as they climb up the beach.

produces a single long wave followed by an oscillatory tail. A *solitary wave-like* trajectory is a solution of (5) but with different S and T than for solitary waves.

Figure 4 shows one wave hierarchy that is produced when the generation time is kept constant at $T = 15.0$ and the generation number is varied. These waves were generated at depths ranging from $d = 11.74\text{cm}$ to $d = 25.53\text{cm}$. Waves generated with $S/d < 0.7$ are nonbreaking, while waves produced with $S/d > 2.0$ are breaking/reforming waves or bores.

Many other similar hierarchies were generated. The experiments covered a range of dimensionless times $T\sqrt{g/d}$ from 3.388 to 55.966 and a range of generation numbers $S/(T\sqrt{g/d})$ from 0.01 to 1.10. Small generation numbers ($S/(T\sqrt{g/d}) < 0.10$) resulted in waves that never broke and in small runup heights ($R/d < 0.22$) while larger generation numbers ($S/(T\sqrt{g/d}) < 0.40$) resulted in waves that broke as they climbed up the beach and in larger runup heights ($R/d < 0.75$). Larger numbers ($Fr < 0.70$) produced waves that broke before reaching the beach, reformed and then broke again as they climbed up the beach. Relatively large generation numbers ($Fr < 0.80$) produced waves that were generated broken and propagated broken without ever reforming. These waves attained the highest runup distances $R/d \approx 1$. It is really surprising how well these values correspond to the values obtained with the ramp trajectory in section 3.1. Runup saturation was again observed; increasing the generation number beyond $Fr = 0.80$ did not result into higher runup heights.

Figure 5 presents the variation of the runup of the waves generated with the

Figure 4 The wave hierarchy generated with a ramp trajectory with generation time $T\sqrt{g/d} = 7.2$ and different strokes. The profiles were measured at approximately 20 depths away from the wave generator. The profiles are not synchronized in time and their relative positions do not necessarily reflect differences in propagation speeds.

Figure 5 The variation of the normalized runup with the generation number. Type S waves. All waves shown break only as they climb up the beach.

solitary wave-like motion, i.e., equation (5) with the generation number.

3.3 Comparison with solitary waves.

It is interesting to compare the data described in section (3.1) and (3.2) with data for Boussinesq solitary waves. A comprehensive study of solitary wave runup has been presented in Synolakis (1987,1987). Figure 6 presents the variation of the normalized runup with the generation number for type R waves, type S waves and for solitary waves. It appears that for a given generation number and regardless of the generation time and the trajectory used, the solitary waves always attain the highest runup distances. This observation hints that solitary waves may indeed be a limiting condition, at least in single long wave runup.

It is important to note that bores of finite volume produce normalized runup distances than are even higher than those produced by solitary waves. This is anticipated and it is not contradictory to the previous discussion; it is not possible to create a solitary wave that is simultaneously a bore. The highest generation number that produces a solitary wave is $Fr = 0.189$. On the other hand it is possible to create bores with generation numbers as high as $Fr = 0.85$. Even then, there is saturation and further increases in the generation number cannot produce higher runup.

These three observations, the fact that details of the plate motion are important in determining the runup, the fact that solitary waves provide a limiting condition

for the runup of long waves that break on the beach and the fact that the bore runup is saturated, suggest that there might exist some dimensionless number such that solitary waves assume the highest value of this number. This question will be explored next.

Figure 6 The variation of the normalized runup with the the generation number. Breaking type R, S waves and solitary waves. The solid line is the line of best fit for the solitary wave data and it is given by $R/d = 1.739Fr^{0.518}$.

4. The runup number.

In attempting to determine a single parameter to describe the process, it is instructive to consider the kinematic analogy of a material particle moving up a frictionless inclined plane. Suppose that a particle of mass m starts climbing up a ramp of slope $\tan\beta$ with horizontal momentum mV . As the particle climbs up, the component of the body force in its direction of motion acts to reduce its momentum. Newton's law implies that $dV/dt = -g \sin\beta$. The maximum elevation the particle will reach is $R = V^2/2g$. The same result can be arrived at by using an energy argument. It is therefore likely that two important motion invariants are the particle's energy and momentum.

The kinematic analogy cannot be carried further; as a wave climbs up a beach reflection continuously reduces its momentum, while wave breaking dissipates its energy. Friction dissipates both momentum and energy. However, it is well known that these processes are slowly acting in extremely long waves such as tsunamis. I will therefore proceed to derive momentum and energy scales that can be used in the derivation of motion invariants.

Consider a single long wave with horizontal momentum M_x per unit mass and per unit width incident upon the sloping beach. The wave attains a maximum

runup height R . The basic variables are R, g, M_x and they can produce only one group, $Rg^{\frac{1}{2}}/M_x^{\frac{2}{3}}$. If one uses the kinetic energy per unit mass and per unit depth as an independent variable, dimensional analysis suggests the group $Rg^{\frac{1}{2}}/\mathcal{E}^{\frac{1}{2}}$. †

The horizontal momentum per unit width and per unit mass is given by $M_x = \int_{\mathcal{V}} u_x d\mathcal{V}$ where \mathcal{V} is the volume occupied by the wave and u_x is the horizontal velocity. To calculate this integral detailed amplitude and velocity data are needed. However since the wavemaker displaces a volume Sd per unit width and since S/T is a measure of the velocity imparted to the motion, an estimate of the momentum of the wave motion is S^2d/T . This leads to a dimensionless momentum invariant $\mathcal{R} = Rg^{\frac{1}{2}}/(S^2d/T)^{\frac{2}{3}}$. This parameter will be referred to as the runup number.

To determine whether this parameter is motion invariant, it is necessary to examine its variation with other independent parameters. Repeating the dimensional analysis of section 2 one obtains

$$\mathcal{R} = \frac{Rg^{\frac{1}{2}}}{(S^2d/T)^{\frac{2}{3}}} = \mathcal{F}\left(\beta, \frac{(S/T)d}{\mu/\rho}, \frac{S}{T\sqrt{gd}}, \frac{S}{d}\right). \quad (6)$$

Figure 7 presents the variation of the runup number with three of the parameters in equation (6) for type R waves. With the exception of bores of finite volume, the runup number does seem to vary very little. Figure 8 presents the variation of the runup number for type S waves. The runup number variation is greater than it is for type R waves; still it only ranges from $\mathcal{R} = 0.8$ to $\mathcal{R} = 1.2$.

Figure 9 presents the runup number variation with the generation number for all wave types previously described. ‡ The figure suggests that the runup number might not be a true motion invariant, in the sense that it varies from $\mathcal{R} = 0.7$ to $\mathcal{R} = 1.3$. (However, the scatter seen is within the margin of experimental error.) More important, the figure also suggests that solitary waves have the highest runup number $\mathcal{R} = 1.30$, implying that indeed solitary waves may provide a limiting condition for wave runup.

† From this point on, I will discuss the influence of the momentum of generation only. The analysis presented in Synolakis (1986) suggests that the motion invariant derived from the momentum describes the process further better than the motion invariant derived from energy.

‡ Figure 9 also includes data for type P waves, which are waves generated with a parabolic trajectory. In the interest of brevity these waves are not in discussed in detail here. Refer to Synolakis (1986) for tables of data and for a description of the experiments.

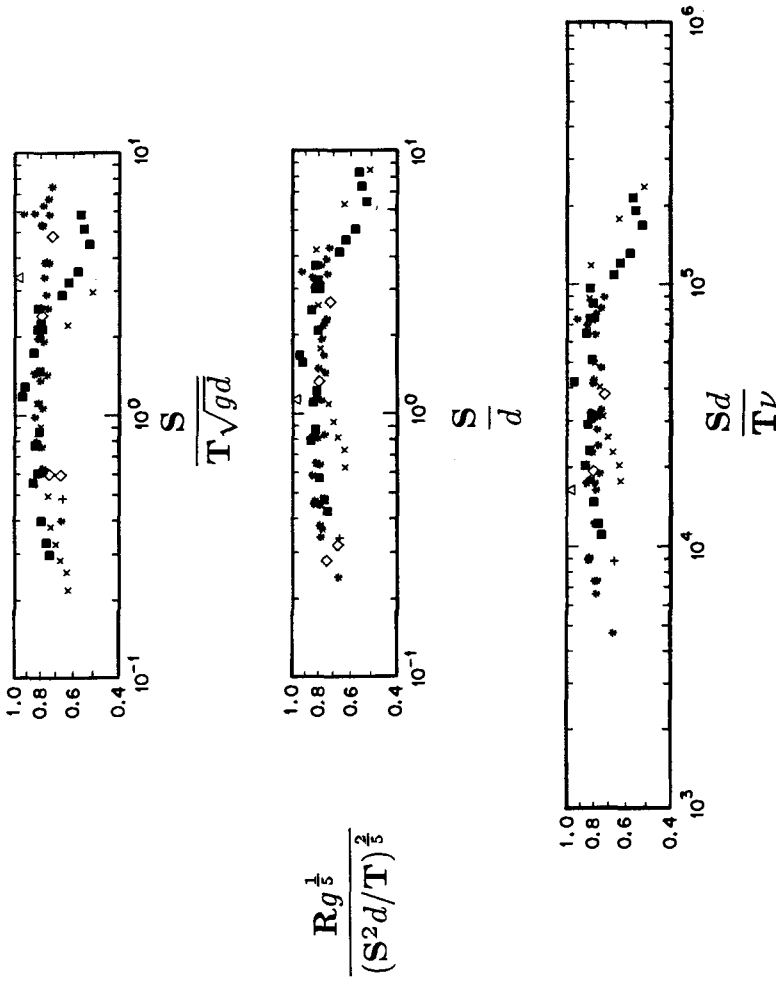

Figure 7 The variation of the runup number with the generation number (a), with the normalized stroke (b) and with the Reynolds number (c). Type R nonbreaking, breaking, breaking/reforming and bores of finite volume.

Figure 8 The variation of the runup number with the stroke (a) and with the generation number (b). Type S breaking waves.

Figure 9 The variation of the runup number with the generation number. Type R, S, P waves and solitary waves.

5. Discussion.

The data presented clearly demonstrate that solitary waves are a limiting condition for wave runup on a sloping beach. For a given generation number the solitary waves attain the highest runup distances regardless of the generation times and trajectory type. Also solitary waves have the highest runup number of all long waves described in this study. One can only speculate why this should be the case.

Arbitrary plate motions produce either single long waves that may be non-breaking, breaking, or bores followed by an oscillatory train or solitary waves. It is reasonable to expect that the runup of a wavetrain will be primarily affected by the runup of the leading wave that emerges from the wavetrain. † The momentum of this wave is less than the momentum that was imparted to the fluid during wave generation. Had all the momentum at generation been used to produce a solitary wave, then this wave would have a larger waveheight and it would attain higher runup distances than the leading wave emerging from a long wavetrain with the same momentum.

This is a very exciting result. It implies that it might be possible to determine

† This analysis is consistent with nonlinear dispersive theory that predicts that any long wavetrain of positive volume will fission into a series of solitons given a sufficiently large propagation distance.

the highest possible runup distance that a wave motion of a given momentum distribution may attain by simply calculating the runup of the solitary wave generated with the same total momentum. Whether this result is true for natural beaches † and whether it is true for three-dimensional topographies remains to be established. However it does suggest that it might be possible to obtain reliable predictions of the coastal effects of tsunamis using solitary wave theory.

6. Conclusions.

There are three major conclusions based on the data on the 1 : 19.85 beach.

- 1) On a given beach, there are maximum runup values that a wave may attain depending on its breaking character, i.e., whether a wave is nonbreaking, breaking, breaking/reforming or a bore of finite volume.
- 2) The generation characteristics of a long wave determine its runup at finite propagation distances. In particular if the momentum scale is estimated using the generation time and stroke, the resulting dimensionless group, the runup number, might be a motion invariant. The runup number for the 1 : 19.85 beach is given by

$$\mathcal{R} = \frac{Rg^{\frac{1}{5}}}{(S^2d/T)^{\frac{2}{5}}} = 1.023 \pm 0.3.$$

The exact value of the generation number depends weakly on the generation time.

- 3) Breaking solitary waves have the highest possible runup number among all other single long waves, thereby providing a limiting condition for long wave runup.

† Even though this discussion implies runup saturation, there is little evidence ((Huntley et al, 1977, Guza and Thornton, 1982) that there is runup saturation in periodic waves up natural beaches.

CHAPTER 15

Coherent Eddies Induced by Breakers on a Sloping Bed

Nobuhiro Matsunaga* , Kosei Takehara** and Yoichi Awaya***

Abstract

The separation of boundary layer occurs periodically near a breaking point when incident waves climbing up a sloping bed are about to break. Not the breaker but the separation forms an unsteady coherent eddy, which suspends a large amount of bed material. A row of steady vortices has been found along the water surface of an offshore zone. Its formation is due to the shear instability between shoreward steady flow induced near the bed and offshore steady flow near the water surface. Moving in the offshore direction, the steady vortices repeat amalgamation each other and increase their intervals at the order of mean water depth. They decay after reaching to the region where the shear rate is not enough between the two steady flows. This shear instability may be excited by the periodic separation of boundary layer.

1. Introduction

Recently, the velocity in nearshore zone has been measured vigorously through field and laboratory investigations in order to reveal the mechanism of suspension and sediment transport or to understand the process of water exchange between nearshore zone and offshore. Many researchers (e.g., Mizuguchi, 1986 ; Okayasu, et al., 1986) have the idea that turbulence by breakers lifts up much bed material, and their attention has focused on coherent eddies in surf zone. Miller (1976) showed the formation of breaker vortices on basis of the pattern of entrained air bubbles. Kaneko(1985) confirmed their formation by tracing the paths of polystyrene beads. Nadaoka(1986) has suggested the existence of oblique eddies from bubble patterns. However, the question that the flow drawn schematically by him forms truly in surf zone will remain until it becomes clear that the ensemble-averaged behavior of individual tracers has such a coherent, rotational structure.

We often observe that a large amount of bed material has been already rolled up at the breaking point when incident waves are about to break. The purposes of this paper are to reveal experimentally the mechanism of this suspension and to show the qualitative characteristics of a vortex train induced in an offshore zone, which has been supposed to be irrotational flow region.

2. Experimental Methods

Figure 1 shows schematically an experimental apparatus. The wave tank was 12 m long, 0.4 m deep and 0.15 m wide. It was made of transparent acrylic plates and equipped with a sloping bed. Two-dimensional regular waves were formed by oscillating a flap. The behaviors of flow were observed near a breaking point and in offshore zone.

Figure 1. Experimental apparatus.

(a) Motor; (b) wave generator; (c) wave tank;
(d) wave gauges; (e) sloping bed.

Near the breaking point, turbulent flow by a plunging breaker was investigated by means of both velocity measurement and flow visualization. The slope θ of the bed was 0.056 and the wave period T was 1.3 s. Figure 2 shows the measuring points and the level of wave crest. The points P.P. and B.P. indicate the plunging point and breaking point, respectively. The velocity measurement was carried out by using a single-component Lazer-Doppler velocimeter of forward scattered fringe mode. Therefore, the horizontal and vertical velocities had to be measured separately under the same hydraulic conditions. Two capacitance-type wave gauges were used for the measurement of wave profiles. One was placed right above the measuring point of velocity and the other was fixed at an offshore position. Signals from the L.D.V. and wave gauges were recorded simultaneously by a data recorder. They were digitized; the sampling time and number were 8/1000 s and 16,384, respectively. Flow patterns were visualized by using granules of aniline blue, condensed milk and saw dust as a tracer.

The flow in offshore zone was observed only by means of flow visualization. The value of θ was 0.043. The period T ranged from 0.55 to 2.0 s. Granules of aniline blue were used as a tracer and were scattered on the water surface of

Figure 2. Measuring points and wave crest level. (P.P. indicates the punging point and B.P. the breaking point.)

the offshore zone. All the flow patterns were photographed instantaneously through a side wall of the tank by using a 35mm camera, which was at rest with respect to it. The offshore side is on the right in all these photos.

3. Results and discussion

Figures 3(a) to (d) show the patterns of secondary steady flow induced near the breaking point. Mean velocity vectors are drawn in figure 3(a). The steady flow rises at the breaking point and runs along the water surface. Shoreward steady flow forms along the boundary layer of the offshore zone (e.g., Longuet-Higgins 1953). It is therefore seen that the breaking point is a separation point of the steady flow. Figure 3(b) shows a lift-up pattern of condensed milk immediately after the start of oscillation. The tracer was precipitated beforehand near the breaking point. Here, t is the time elapsed since the start of oscillation and T the wave period. A large amount of the tracer is lifted up at the breaking point without running down along the bed of the offshore zone, and it is transported along the water surface. This pattern agrees well with that shown in figure 3(a). Figure 3(c) was taken when $t/T = 92$. A row of vortices with the clockwise rotation is seen in the offshore zone. The formation mechanism and formation region of this vortex train will be discussed later in detail. Figure 3(d) is a close-up view of the boundary layer separation. Aniline blue dye was used as a tracer. The dye dropped on the bed of the offshore zone is transported onshore by the shoreward steady flow

(d)

Figure 3. Steady flow patterns induced near the breaking point. (Arrow (1) indicates the separation of boundary layer and arrow (2) the trace of dye along the bed.)

Figure 4. Velocity and flow patterns when an incident wave is about to break. Scale bar is 10 cm.

along the boundary layer, and separates at the breaking point just before breaking. It should be noted that the run-up of tracer along the bed is not observed in surf zone owing to the separation. This visualized result supports also the pattern shown in figure 3(a).

Figure 4(a) shows the ensemble-averaged velocity pattern at a phase just before breaking. Strong upward orbital motion is seen at the front of wave crest. Figure 4(b) is taken at almost the same phase as figure 4(a). Saw dust is lifted up owing to both the separation of boundary layer and the orbital motion.

Figure 5(a) is the ensemble-averaged velocity pattern at a phase immediately after breaking. Arrow (1) indicates a flow pattern induced by plunging. It should be emphasized that the flow does not form a complete rotational pattern since its direction is shoreward near both the bed and water surface. Arrow (2) indicates a vortical pattern with the clockwise rotation. The formation of this coherent eddy is closely related to the separation of boundary layer. From these reasons, therefore, it may properly be called the 'backwash vortex', which was found by one of the authors(1979, 1981). Figure 5(b) shows an instantaneous

Figure 5. Velocity and flow patterns immediately after breaking. Scale bar is 10 cm.

flow pattern at almost the same phase as that of figure 5(a). Two lift-ups of saw dust are seen as indicated by arrows (1) and (2). The lift-up shown by arrow (1) seems to be due to plunging breaker. On the other hand, considering that the suspension shown by arrow (2) has the clockwise rotation and forms near the breaking point every wave period, we can guess that it is generated by the backwash vortex.

Figures 6(a) and (b) show velocity and flow patterns, respectively, when a wave trough passes through the breaking point. Both the patterns agree well and the coherent suspensions have been already wiped out by the orbital motion.

Now, let us discuss about the vortex train appearing in offshore zone. Figure 7 shows a steady flow pattern induced along the water surface of offshore zone. The breaking point was at 0.68 m shoreward from the position E and the intervals between adjacent positions was 0.5 m. A wavy flow pattern is seen in the top photo. Between the positions D and B, the wavy pattern develops to a row of vortices with the clockwise rotation. Their intervals increase with the increase of water depth. As shown in the bottom photo,

(a)

(b)

Figure 6. Velocity and flow patterns when a wave trough passes through the breaking point.

the vortical pattern disappears in the region seaward from B. In the following discussion, this vortex will be called an 'offshore vortex'.

In figures 8(a) to (f), the process is shown in which the intervals of offshore vortices increase in the seaward direction. Here, t is the time passed from the photographing of figure 8(a). Let us focus attention on the two offshore vortices indicated by the arrows. Moving in the seaward direction, the two vortices approach gradually each other as shown in figures 8(b) to (d). Figure 8(e) shows that they have become one offshore vortex after their amalgamation. In figure 8(f), we can see the offshore vortices rearranged at the intervals of the order of mean water depth.

Let us consider about the formation region of the offshore vortex train. It may be expressed by the following function.

$$\text{Formation region} = f(h, L, H, T, C, g)$$

Here, h is the mean water depth, L the wavelength, H the wave height, T the wave period, C the phase velocity of incident waves and g the acceleration of gravity. In this

expression, it has been assumed that the bed slope and the kinematic viscosity of fluid are constant. If the relation of $C = L/T$ and the dispersion relation are taken into account, the function is simplified as $g(h, L, H, g)$. Therefore, non-dimensional quantities to describe the formation region become h/L and H/L .

In figure 9, the formation region is examined by plotting H/L against h/L . The parameter H_0/L_0 is the steepness of deep water waves. The open circles indicate the formation of offshore vortices and the solid circles mean that the vortices are not observed. Regions (I), (II) and (III) are bounded by the solid lines. Line (1) expresses an empirical relationship between wave height and mean water depth at breaking points. Region (I) is the formation region of the vortex train. Region (II) indicates the region where the offshore vortices decay as shown in the bottom photo of figure 7. In region (III), no laminar vortical pattern is observed because of the strong diffusion due to high steepness of waves.

Figure 10 shows schematically the flow patterns induced in the offshore zone on the basis of the qualitative results mentioned above. The backwash vortex forms periodically near the breaking point owing to the separation of boundary layer. In the offshore zone, the train of offshore vortices develops in the seaward direction from the breaking point. Its formation is due to the shear instability between the shoreward and seaward steady flows, which are indicated by the arrows. This instability may be excited by the periodic separation. The offshore vortices increase their intervals as they move in the seaward direction. However, they decay after reaching to the region where the shear rate is not enough between the two steady flows.

Figure 10. Schematic diagram of coherent eddies induced by breakers.
(a) backwash vortex; (b) offshore vortices.

In conclusion, the authors suggest that the separation of boundary layer near the breaking point and the offshore vortex train would be very important in the process of near-shore sediment transport.

Acknowledgments

We would like to express our sincere thanks to Dr. T. Komatsu of Kyushu University and Professors H. Honji of Kyushu University and P. D. Komar of Oregon State University for valuable suggestions. A grant from the foundation 'Hattori-Hokokai' is also acknowledged.

CHAPTER 16

Wide-Angle Water Wave Models Using Fourier Method

Robert A. Dalrymple,¹ Member, ASCE
Kyung Duck Suh,² Associate Member, ASCE

Abstract: Two Fourier models for the propagation of surface waves are reported, which are theoretically valid for angles of propagation up to $\pm 90^\circ$ with respect to normal incidence. This is a great improvement in comparison with the present parabolic models. The first model is based on the assumption of straight and parallel depth contours, and the second one is the extension to the case of irregular bathymetry.

1 Introduction

The parabolic equation method has proven to be a convenient and rapid method for modelling the propagation of surface waves over water of varying depths, including such important phenomena as refraction and diffraction, e.g. Radder (1979), Booij (1981), Kirby & Dalrymple (1983), Liu & Tsay (1984). The small-angle approximation of this method, however, leads to errors if the wave direction deviates largely from the assumed propagation direction like the waves diffracted behind a breakwater, for example.

Very recently Dalrymple & Kirby (1988) developed a wave propagation model valid for angles of propagation up to 90° with respect to the assumed propagation direction (positive x direction in this paper), based on the assumption that the depth contours are straight and parallel in the y direction. This model was extended to the case of irregular bathymetry by Dalrymple *et al* (1988). In Dalrymple & Kirby, the incident wave train at $x = 0$ is decomposed into directional modes, or an angular spectrum, by taking the Fourier transform of the wave train in the y direction, and each directional mode propagates in the x direction only undergoing refraction and shoaling. In Dalrymple *et al*, however, bottom irregularities are shown to interact with nonzero directional modes and to force the evolution of other directional modes, even if they are initially of zero magnitude. In this paper, these two models are briefly summarized and various examples are presented.

2 Linear Fourier model – Straight and parallel contours

The mild-slope equation developed by Birkhoff (1972) can be written, on a beach with straight and parallel (in the y direction) depth contours, as

$$(CC_g\Phi_x)_x + CC_g\Phi_{yy} + k^2CC_g\Phi = 0 \quad (1)$$

¹Prof., Dept. of Civ. Engrg., Univ. of Delaware, Newark, DE 19716.

²Res. Asst., Dept. of Civ. Engrg., Univ. of Delaware, Newark, DE 19716.

where C and C_g are the phase and group velocities, respectively, k is the wavenumber, and $\Phi(x, y)$ is the free surface elevation obtained by dropping the harmonic time dependence. The Fourier transform of the above equation in the y direction leads to the decomposition of the potential into directional modes

$$(CC_g \hat{\Phi}_x)_x + (k^2 - \lambda^2)CC_g \hat{\Phi} = 0 \tag{2}$$

where the caret denotes a variable in the Fourier space and λ is the continuous Fourier parameter.

Splitting the potential into the forward propagating and backscattered potentials and neglecting the assumed small backscattered wave (see Dalrymple & Kirby (1988) for details), the propagation model for the forward propagating wave (denoted by the superscript +) is obtained as

$$\hat{\Phi}_x^+ = i\sqrt{k^2 - \lambda^2} \hat{\Phi}^+ - \frac{[CC_g \sqrt{k^2 - \lambda^2}]_x}{2CC_g \sqrt{k^2 - \lambda^2}} \hat{\Phi}^+. \tag{3}$$

This equation can be solved analytically to give the solution

$$\hat{\Phi}^+(x, \lambda) = \hat{\Phi}^+(0, \lambda) \left[\frac{(CC_g)_o \sqrt{k_o^2 - \lambda^2}}{CC_g \sqrt{k^2 - \lambda^2}} \right]^{1/2} e^{i \int \sqrt{k^2 - \lambda^2} dx} \tag{4}$$

where the subscript o indicates initial conditions at $x = 0$. The bracketed term contains the shoaling and refraction coefficients associated with gradual water depth changes (e.g. Dean & Dalrymple (1984)).

Under the assumption that the model domain is laterally periodic, the problem can be approximated in the discrete Fourier space. The domain is discretized in the y direction by N equidistant points, with spacing $\Delta y = \ell / (N - 1)$ where ℓ is the width of the domain. The velocity potential $\Phi^+(x, y)$, numerically defined only on these points, can be transformed into discrete Fourier modes by

$$\hat{\Phi}^+(x, n) = \frac{1}{N} \sum_{j=0}^{N-1} \Phi^+(x, j\Delta y) e^{-in\lambda j\Delta y}, \quad n = 0, \pm 1, \dots, \pm \left(\frac{N}{2} - 1\right), -\frac{N}{2}. \tag{5}$$

The inversion formula is

$$\Phi^+(x, j\Delta y) = \sum_n \hat{\Phi}^+(x, n) e^{in\lambda j\Delta y}, \quad j = 0, 1, \dots, (N - 1) \tag{6}$$

where

$$\lambda = \frac{2\pi}{N\Delta y} \tag{7}$$

Figure 1: Diagram of the Fourier decomposition of the wave field on a row with an angular spectrum (with lateral wavenumbers, $n\lambda$, $n = 0, \pm 1, \pm 2, \dots$).

which is different from the continuous Fourier parameter λ used before. Subsequently, λ is defined by (7) if it is used in the discrete Fourier space. These transforms can be performed efficiently by using a fast Fourier transform (FFT for short) with $N = 2^p$ where p is a positive integer. Now the equation (4) can be expressed, in the discrete Fourier space, as

$$\hat{\Phi}^+(x, n) = \hat{\Phi}^+(0, n) \left[\frac{(CC_g)_o \sqrt{k_o^2 - (n\lambda)^2}}{CC_g \sqrt{k^2 - (n\lambda)^2}} \right]^{1/2} e^{i \int \sqrt{k^2 - (n\lambda)^2} dx}, \tag{8}$$

$$n = 0, \pm 1, \pm 2, \dots, \pm \left(\frac{N}{2} - 1 \right), -\frac{N}{2}.$$

Here $\hat{\Phi}^+(x, n)$ denotes the directional modes of the wave field on a row, each has the direction depicted in Fig. 1. As $n\lambda$ exceeds k in magnitude, $\sqrt{k^2 - (n\lambda)^2}$, the wavenumber in the x direction, becomes imaginary, indicating evanescent modes which decay exponentially in the propagation direction. Usually the evanescent modes have negligible amplitude with sufficiently large N , so only the progressive modes are carried in the computation.

2.1 Periodic gaps in breakwaters

For periodic gaps of width $2a$ in breakwaters, the initial condition is given by the Kirchoff condition on Φ_x^\pm along the breakwater, i.e.

$$\Phi_x^+(0, y) = \begin{cases} e^{i\lambda_o y}, & |y| < a \\ 0, & |y| > a \end{cases} \tag{9}$$

where λ_o is the projection of the wavenumber in the y direction at $x = 0$, that is, $\lambda_o = k_o \sin \theta_o$, where θ_o is the incident wave angle, and the origin of the coordinates is located at

Figure 2: Instantaneous wave field behind periodic breakwater gaps on a sloping beach. The line denotes a wave ray, emanating from the center of one of the gaps. Depicted area is $405.75 \times 692.48 \text{ m}$. (reprinted with permission of Cambridge University Press)

the center of one of the gaps. $\hat{\Phi}_x^+(0, n)$ is obtained by an FFT of (9), and then $\hat{\Phi}^+(0, n)$ is computed by

$$\hat{\Phi}_x^+(0, n) = i\sqrt{k_o^2 - (n\lambda)^2} \hat{\Phi}^+(0, n) \tag{10}$$

which is the reduced form of (3) on constant depth. Finally $\Phi^+(0, y)$ is obtained by an inverse FFT of $\hat{\Phi}^+(0, n)$.

The breakwater gap shown in Fig. 2 is backed by a plane sloping beach with a slope $h_x = 0.0308k_o h_o$ where $h_o = 10 \text{ m}$ is the water depth at the location of breakwater. The gap has a width of 100 m . The incident wave field has a 9 sec wave period and a 45° angle of incidence. $N = 128$ and $\Delta x = \Delta y = 5 \text{ m}$. In Fig. 2, the instantaneous wave field on the sloping beach is shown. The influence of wave refraction is clear with the maximum of the diffraction pattern turning towards the shoreline normal. The influence of the periodic boundary conditions is also apparent as the waves from the upwave gap have intruded into the figure, yielding a short-crested sea state near the middle of the figure. The wave ray shown in the figure was determined independently using the method outlined in Mei (1983). The diffracting wave train follows the wave ray very well.

2.2 Intersecting waves past a breakwater

The specification of the incident wave field can be quite general. As a simple example, two synchronous wave trains of 9 sec period are assumed to be incident on a breakwater (386 m in length, lying on the y axis) at $\pm 30^\circ$ to each side of the x axis, creating a short-crested sea state in the absence of the breakwater, as shown in Fig. 3. Behind the breakwater, centered in the middle of the y axis, the two shadow zones cast by the two wave trains

Figure 3: Instantaneous wave field behind an offshore breakwater created by two intersecting wave trains. The breakwater length is 386 m and the displayed area is 1016 m wide. (reprinted with permission of Cambridge University Press)

result in a long-crested sea state in these zones, as only one of the wave trains is blocked by the breakwater.

Extension to a truly directional sea state composed of many frequencies is straightforward. It is a matter of superposing the requisite number of wave trains with different frequencies and appropriate random phases, since for each frequency the evolution of the directional spectrum is computed in the present model.

3 Nonlinear Fourier model on irregular bathymetry

The governing equation is again taken to be the mild-slope equation

$$\nabla \cdot (CC_g \nabla \Phi) + k^2 CC_g \Phi = 0. \quad (11)$$

The wavenumber k is related to the wave angular frequency ω and the local water depth h by the linear dispersion relationship

$$\omega^2 = gk \tanh kh \quad (12)$$

where g is gravity. This relation is modified later to incorporate nonlinearity in the model.

Using the definitions of $p(x, y) = CC_g$ and $\phi = \sqrt{p} \Phi$ as in Radder (1979), the mild-slope equation becomes an Helmholtz equation

$$\nabla^2 \phi + k_c^2 \phi = 0 \quad (13)$$

where

$$k_c^2 = k^2 - \frac{\nabla^2 \sqrt{p}}{\sqrt{p}}. \tag{14}$$

For the convenience of later splitting of the solution, we define a laterally averaged wavenumber, \bar{k} , as

$$\bar{k}^2 = \frac{1}{\ell} \int_0^\ell k_c^2 dy \tag{15}$$

so that

$$k_c^2 = \bar{k}^2 (1 - \nu^2) \tag{16}$$

where

$$\nu^2 = 1 - \frac{k_c^2}{\bar{k}^2} \tag{17}$$

whose magnitude is usually much smaller than unity if the topography does not deviate drastically from straight and parallel contours. Note that \bar{k}^2 is a function of x only and the variability of depth in the y direction is contained in $\nu^2(x, y)$. Substituting (16) into (13) gives

$$\nabla^2 \phi + \bar{k}^2 \phi - \bar{k}^2 \nu^2 \phi = 0. \tag{18}$$

The Fourier transform of (18) in the y direction leads to the equations for directional modes

$$\hat{\phi}_{xx} + (\bar{k}^2 - \lambda^2) \hat{\phi} - \bar{k}^2 F(\nu^2 \phi) = 0. \tag{19}$$

Note that the Fourier transform of $(\nu^2 \phi)$ involves ϕ in the real space. Again splitting the potential and neglecting the backscattered wave, the propagation model for the forward propagating wave is obtained as

$$\hat{\phi}_x^\pm = i\sqrt{\bar{k}^2 - \lambda^2} \hat{\phi}^\pm - \frac{[\sqrt{\bar{k}^2 - \lambda^2}]_x}{2\sqrt{\bar{k}^2 - \lambda^2}} \hat{\phi}^\pm - \frac{i\bar{k}^2 F(\nu^2 \phi^\pm)}{2\sqrt{\bar{k}^2 - \lambda^2}}. \tag{20}$$

The second term on the right side represents the shoaling/refraction of each wave mode on the laterally averaged depths. The $F(\nu^2 \phi^\pm)$ term represents the interaction between

surface wave and the lateral bottom variation, which will be examined in detail later in this section. For straight and parallel bottom contours, this term vanishes and the above equation reduces to (3).

In the discrete Fourier space, (20) can be approximated as

$$\hat{\phi}_x^+ = i\sqrt{k^2 - (n\lambda)^2} \hat{\phi}^+ - \frac{\left[\sqrt{k^2 - (n\lambda)^2} \right]_x}{2\sqrt{k^2 - (n\lambda)^2}} \hat{\phi}^+ - \frac{i\bar{k}^2 F_n(\nu^2 \phi^+)}{2\sqrt{k^2 - (n\lambda)^2}}, \quad (21)$$

$$n = 0, \pm 1, \pm 2, \dots, \pm\left(\frac{N}{2} - 1\right), -\frac{N}{2}$$

associated with the discrete Fourier transforms (5) and (6). F_n denotes the n^{th} Fourier component. The above equation represents N first-order ordinary differential equations in x , which are solved by a fourth-order Runge-Kutta method. The details of finite differencing and stability analysis of the numerical method are referred to Dalrymple *et al* (1988). The numerical procedure involves calculating the Fourier modes by marching along the x direction. However, $F_n(\nu^2 \phi^+)$ in the last term in (21) should be calculated in the real domain, so, at each step, recourse to the real domain by the inverse FFT is needed.

The Fourier model (21) is linear since it is based on the linear mild-slope equation (11). In order to incorporate nonlinearity in the model, an empirical nonlinear dispersion relation proposed by Kirby & Dalrymple (1986) is used, which approximates the wavenumber for a solitary wave in shallow water and, in deep water, provides the wavenumber corresponding to the Stokes third-order theory, given by

$$\omega^2 = gk[1 + f_1(ka)^2 D] \tanh[kh + f_2(ka)] \quad (22)$$

where a is the local wave amplitude and

$$f_1(kh) = \tanh^5 kh, \quad (23)$$

$$f_2(kh) = \left[\frac{kh}{\sinh kh} \right]^4, \quad (24)$$

$$D = \frac{\cosh 4kh + 8 - 2 \tanh^2 kh}{8 \sinh^4 kh}. \quad (25)$$

The calculation of the wavenumber k using (22) needs iteration because of the dependence of the wavenumber on wave height. Thus, first we perform the computation with the wavenumber given by the linear dispersion relation (12). Using the calculated wave height, then, the wavenumber is corrected by the nonlinear dispersion relation (22). This procedure is repeated until convergence is achieved.

3.1 Interaction between surface wave modes and the bottom variation

The term $F_n(\nu^2 \phi^+)$ in (21) represents the interaction between the directional wave modes and the lateral bottom variation, which can force the evolution of the various directional

modes, even if they are initially of zero magnitude. In order to examine this mechanism, we express $F_n(\nu^2\phi^+)$, in terms of periodic convolution, as

$$F_n(\nu^2\phi^+) = \frac{1}{N} \sum_{m=0}^{N-1} \hat{\nu}^2(x, m\lambda) \hat{\phi}^+(x, (n-m)\lambda) \quad (26)$$

where $\hat{\nu}^2(x, m\lambda)$, $m = 0$ to $N - 1$, is the discrete Fourier series obtained by the Fourier transform of $\nu^2(x, y)$ in the y direction. This equation states that the m^{th} bottom mode $\hat{\nu}^2(x, m\lambda)$ triggers the $(n - m)^{\text{th}}$ wave mode to evolve the n^{th} wave mode.

Figure 4: Bottom geometry and the initial condition of the wave field for the example of wave propagation over a bathymetry consisting of laterally periodic ridges and troughs.

In order to illustrate this more explicitly, we have applied the model to a monochromatic wave train travelling over a bed whose depth is constant in the x direction but varies sinusoidally in the y direction, creating transverse bottom ridges. These ridges begin at $x = 0$. In this particular example, the second term on the right side in (21) vanishes. The mean water depth is 10 m and the wavelength and amplitude of the bed are 640 m and 2 m, respectively, as shown in Fig. 4. At $x = 0$, a plane wave of 8 sec period and 1 m amplitude enters the domain at an incident angle of 12.8°. We have taken $\Delta x = 5$ m and $\Delta y = 10$ m to make a grid of 500 × 128 rows over 2,500 × 1,280 m model area, so that the wave mode at $x = 0$, $\hat{\phi}^+(0, n\lambda)$, is nonzero for $n = 4$ and zero for all other modes, while the bottom mode $\hat{\nu}^2(x, m\lambda)$ are appreciable for $m = 2, 4, 6, (N - 6), (N - 4), (N - 2)$ and are negligibly small for all other modes as shown in Fig. 5. At the first step, these bottom modes interact with $\hat{\phi}^+(0, 4\lambda)$ to generate the wave modes of $n = 6, 8, 10, -2, 0, 2$, respectively, which were initially of zero magnitude. Note that in an FFT, the following changes are made: $\hat{\nu}^2(x, (N - m)\lambda) = \hat{\nu}^2(x, -m\lambda)$. The mechanism for the subsequent generation of new directional modes is very complicated. Note that only the even-number modes are generated in this particular example.

Figs. 6 (a)–(d) show the amplitude spectra of the progressive modes at different sections. The wave field at $x = 0$ (Fig. 6 (a)) is described by single wave mode, $\hat{\phi}^+(0, 4\lambda)$, which is propagating at 12.8° to the x axis. The generation of new modes near the initial condition is shown in Figs. 6 (b)–(c), and the broad spectrum at $x = 2,500$ m is shown in Fig. 6 (d). Again observe that the odd-number modes are never generated.

Figure 5: Amplitude spectrum of the bottom modes $\hat{\nu}^2(x, m\lambda)$ for the periodic bathymetry shown in Fig. 4. Note that $\hat{\nu}^2(x, m\lambda)$ is different from the depth mode $\hat{h}(x, m\lambda)$ which gives nonzero values for $m = 2$ and $N - 2$ and zero for all other values of m .

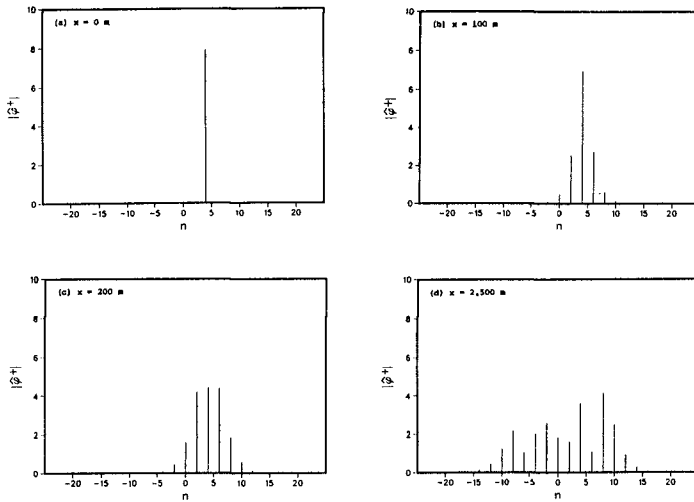

Figure 6: Evolution of the amplitude spectra of the progressive modes at different sections.

Another interesting result in this example is the wave trapping over the ridge as shown in Fig. 7, which is the contour map of the instantaneous free surface elevation at intervals of 0.5 m. The waves passing over the central ridge are focused near $x = 700\text{ m}$, $y = 720\text{ m}$ and turn back to the left. Mei (1983) has discussed this problem based on ray theory. Some of the rays determined by the Mei's method are drawn in Fig. 7. The rays 1, 2 and 8, counting from the left, travel over the wavy bed without being trapped. The rays 3 to 7,

however, are trapped. For these rays computation was stopped at the turning points, where the ray model blows up, but the extrapolation of these rays can explain the wave trapping phenomenon over the ridge in this example.

Figure 7: Instantaneous wave field over periodic ridges and troughs. The lines denote wave rays emanating from $x = 0$ at 12.8° angle of incidence at intervals of 80 m .

3.2 Wave focusing behind a circular shoal

For the purpose of testing the model for the prediction of wave deformation on an irregular bathymetry, we have chosen the experiment reported by Ito & Tanimoto (1972).

The experimental bathymetry consists of a circular shoal resting on a flat bottom $h_1 = 0.15\text{ m}$ as shown in Fig. 8. The water depths in the shoal region are described by

$$h = h_2 + 0.15625[(x - 1.2)^2 + (y - 1.2)^2] \quad (27)$$

where $h_2 = 0.05 \text{ m}$ is the depth at the shoal crest. A monochromatic wave train with the wave height 1.04 cm and the wave period 0.511 sec enters the domain at $\theta_o = 0^\circ$.

Figure 8: Geometry of the computational domain for the experiment by Ito & Tanimoto (1972).

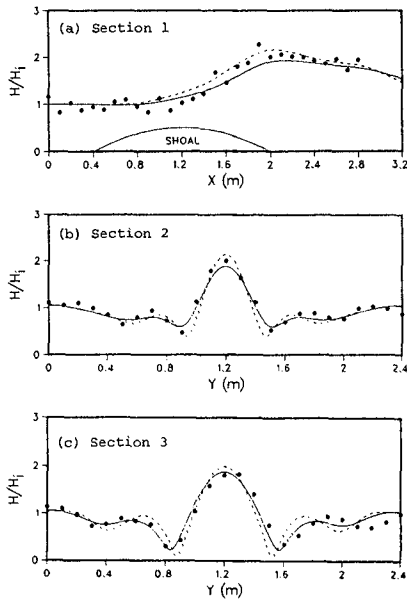

Figure 9: Comparison of the model results against the experimental data by Ito & Tanimoto (1972) in terms of normalized wave height with respect to incident wave height. ● = Experiment, - - - = Linear model, — = Nonlinear model.

For the three different sections indicated in Fig. 8, data from the experiment of Ito & Tanimoto are available. Comparison with the model results along these sections are shown in Figs. 9 (a)–(c) in terms of normalized wave height with respect to the incident wave height. In each figure, linear and nonlinear model results are indicated by dashed and solid lines, respectively, while black dots indicate measured data points. Nonlinear effects reduce the wave heights along the centerline of wave focusing and broaden the region of focused wave so that the diffraction fringes are displaced away from the centerline. Along the centerline (Fig. 9 (a)), data fall between the predictions of the two models, with the nonlinear model slightly underpredicting the data. On section 2 where the cusped caustic is fully developed, again it is difficult to judge which model predicts the data better. However, on section 3 where the wave has passed through the caustic cusp, the nonlinear model predictions and the data points are in much better agreement than the linear model.

Through the above example we have verified that our model is a reasonably good predictor of the wave field development on an irregular bathymetry where the effects of refraction, diffraction and nonlinearity are equally significant. However, that example is not sufficient for showing the ability of the model for a large angle of incidence. The next example we have chosen for this purpose is for the same wave and bottom geometry as those in the above example but different angle of incidence. Due to the axisymmetry of the circular shoal, the wave focusing pattern behind the shoal should be independent of the angle of incidence, if the model predicts it 'correctly'.

The contours of wave height normalized with respect to the incident wave height are shown in Figs. 10 (a) and (b) for $\theta_o = 0^\circ$ and $\theta_o = 45^\circ$, respectively. The right half of the domain in the case of $\theta_o = 45^\circ$ is the extension of the flat bottom. The results of a linear parabolic model are also shown in Fig. 10 (a) as dotted lines for $\theta_o = 0^\circ$ and in Fig. 10 (c) for $\theta_o = 45^\circ$. The difference between the present model and the parabolic one is not significant for $\theta_o = 0^\circ$ even though the entire wave focusing pattern in the parabolic model is shifted slightly backward compared with that in the present model. For $\theta_o = 45^\circ$, however, the parabolic model gives large distortion of the wave focusing pattern. Especially the center line of wave focusing rotates by about 12.5° towards the positive x direction. For the present model, some images of the shoal appear periodically in the y direction and the upper left corner is contaminated by the effects of the upwave shoal. Over the shoal, the asymmetric distortion to the focusing pattern at $\theta_o = 45^\circ$ is apparent. However, the overall wave focusing pattern behind the shoal at $\theta_o = 45^\circ$ is very similar to that at $\theta_o = 0^\circ$, showing that the model works reasonably well for a large angle of incidence.

The height of the shoal in the above example is $2/3$ of the water depth on the flat bottom, indicating an unreasonably high shoal considering the normal situation in real cases. Dalrymple *et al* (1988) have tested the model for shallower shoals and showed that the bigger the shoal height, the bigger the asymmetric distortion to the focusing pattern for the same angle of incidence. They also have presented a simple theoretical analysis regarding the accuracy of the model in terms of lateral depth variation and wave propagation angle, concluding that in order for the present model to be accurate for a large angle of incidence, the lateral depth variation should be small.

Figure 10: For caption see next page.

Figure 10: Wave focusing pattern behind the circular shoal used in the experiment by Ito & Tanimoto (1972). Contours indicate wave height normalized with respect to incident wave height. (a) $\theta_o = 0^\circ$ (— = Present model, = Parabolic model), (b) $\theta_o = 45^\circ$ (Present model), (c) $\theta_o = 45^\circ$ (Parabolic model).

4 Conclusion and discussion

Two wide-angle water wave propagation models using the spectral Fourier method have been reported, one for straight and parallel depth contours and the other for irregular bathymetry. In both of the models, the wave field at the initial row ($x = 0$) is Fourier decomposed into directional modes and the evolution of each mode due to bottom variation is calculated by marching along the x direction; finally, the real wave field is recovered by taking the inverse Fourier transform in the y direction.

All the examples presented are for a monochromatic wave train or two intersecting waves. As demonstrated in the example of two intersecting waves past a breakwater, a directional wave with single frequency can be modelled easily by the present models. If the steady state is assumed so that the interaction among the waves with different frequencies is neglected, the extension of the models to the random directional wave field can be made by superposing the requisite number of waves with different frequencies, with appropriate phases.

Nonlinearity was included in the model by correcting the wavenumbers iteratively using the nonlinear dispersion relationship, (22). Wave-current interaction also could be included by using the following dispersion relationship

$$\sigma = \omega + \vec{k} \cdot \vec{U} \tag{28}$$

where $\sigma = 2\pi/T$ is newly defined as the angular frequency, ω is given by (22), and \vec{U} is the depth-mean current vector which is assumed to be known.

CHAPTER 17

Wave Climate off Rio de Janeiro

Maria Helena Severo de Souza*
Carlos Eduardo Parente Ribeiro**

ABSTRACT

The objective of this work is to understand the evolution and main features of the wave climate in the offshore area off Rio de Janeiro State - Brazil, using point measurements. Several spectral models are compared with the data and criteria based on Jonswap and Mitsuyasu relationships are established to identify situations of combined sea and swell from different directions. The Toba model is used to get friction wind values from the spectra for comparison with measured winds. After understanding the main features of the wave climate and using visual observations for wave direction and the spectral information, a distribution of average energy vs direction is calculated.

1. INTRODUCTION

The offshore area northern off Rio de Janeiro State (fig. 1a) is a big oil production region known as Campos basin. In some locations oil is being exploited in water depths of 400 meters, among the largest in the world and new promising fields shall be exploited above 1000 meters. The design and operation of structures and other oceanic systems for such depths is being a big challenge for ocean engineers and the knowledge of environmental conditions is of paramount importance. Wave data is still scarce in the area mainly that concerned with directional spectra.

Figure 1.a) The Campos basin; b) Offshore plataform PGP-1

*- Researcher, Brazilian Navy Hydrographic Institute

** Associate Professor, COPPE - Federal University of R. de Janeiro. Brazil.

The weather in the basin is dominated by the presence of a tropical anticyclone and periodically visited by cold fronts and polar masses coming from the south.

This work is an attempt to describe the evolution and main features of the wave climate from point measurements and visual wave direction observations. Several criteria are established for the identification of the different situations most of them of combined seas and swell.

2. DATA ACQUISITION AND ANALYSIS

The wave and wind data used in this work was acquired from May 1984 to June 1985 in an offshore platform in the Campos basin (PGP-1) located as shown in fig.1b. The related information is resumed below.

Wave staff:	discrete resistive - magnetic coupling
measurement period:	26.09 minutes
measurement interval:	3 hours
wave direction:	visual observation
wind sensor:	cup anemometer and vane
local depth:	130 mts
FFT analysing period:	17,06 minutes
sampling frequency:	1 Hz
number o samples:	1024
degrees of freedom:	50

Two wavestaffs were used and according to the wave direction the best record was selected.

3. A BRIEF METEOROLOGICAL PICTURE OF THE AREA

The region is deeply influenced by the South Atlantic anticyclone. A typical good weather chart is shown in fig.3a. NE moderate winds and relatively large fetches are common at these times. Polar masses coming from the South reach periodically the region.

Figure 3. a) good weather; b) cold front approaching

The wind changes successively from NE to NW and to SW. With strong SW winds and large fetches, big swells and rough seas occur in the area. Fig.4 shows the cold front approaching, producing a strong, limited fetch, NW wind. After the passage of the cold front, SE winds can blow for hours and even days producing big swells in the region. Fig. 4 illustrates this situation.

Figure 4. cold front passing over Campos basin

4. SPECTRAL MODELS

The meteorological situations can produce a combination of sea and swell from several directions; by fitting spectral models to the data we try to identify these different contributions in order to have a better understanding of the wave climate.

4.1. THE PIERSON-MOSKOWITZ MODEL (PM)

The PM model for well developed seas, proposed in 1964, is used here to indicate a limiting value for the nondimensional peak frequency. Below this value one considers a developed sea and the presence of swell. The formulation is:

$$S(f) = \alpha g^2 (2\pi)^{-4} f^{-5} \exp [-5/4 (f/f_m)^4] , \text{ where:}$$

$$\alpha = 8.1 \times 10^{-3} - \text{Phillips constant;}$$

$$f_m = (2\pi)^{-1} (4 \beta/5)^{1/4} g (U_{19.5})^{-1} - \text{peak frequency;}$$

$$U_{19.5} = \text{wind at 19.5 mts ; } \beta = 0.74$$

$$\tilde{f}_m = f_m U/g - \text{non dimensional frequency}$$

$$\tilde{f}_m = 0.14 \text{ for } U_{19.5} \text{ and } \tilde{f}_m = 0.13 \text{ for } U_{10}$$

4.2. THE JONSWAP (J) MODEL

For fetch limited seas Hasselmann et alli (1973) proposed the JONSWAP model named after an experiment in the North Sea; This model fits a spectrum to the wave data. The formulation is:

$$S(f) = \alpha g^2 (2\pi)^{-4} \exp[-5/4 (f/f_m^2)^{-4}] \gamma \exp[-(f-f_m)^2 / 2\sigma^2 f_m^2] \quad [1]$$

α = scale factor; f_m = peak frequency; γ = scale factor

σ = shape factor

A shape parameter λ is defined as: $\lambda = E f_m^4 / \alpha g^2$ [2]

E = Energy of the spectrum ; α is calculated by:

$$\alpha = (0.65 f_m)^{-1} \int_{1.35 f_m}^{2 f_m} (2\pi)^4 f^5 g^2 \exp[5/4 (f/f_m)^4] S(f) df \quad [3]$$

γ is calculated from α and $S(f)$:

$$\gamma = S(f_m) (2\pi)^4 f_m^5 e^{(5/4)} (\alpha g^2)^{-1} \quad [4]$$

Hasselmann and alli (1976) have shown that for developing seas λ has an average value of 1.3×10^{-4} with a small scatter.

Considering that E and f_m are parameters measured with confidence if the data quality is good. We decide to compare the value of α obtained from relation [3], called now α' , with the one from relation [2] called now α_h .

If there is only a local sea in the area the values of α' and α_h must be very close. If there is a swell mixed with a local sea α' is bigger than α_h . In some situations a peak in the high frequency region due to a mixture of two seas may cause $\alpha_h > \alpha'$. Fig. 5 illustrates these situations.

Figure 5. α' and α_h for different situations

In the last example d) we may have a compensation caused by the two effects and both values can remain very close. This comparison of α_h and α' was used to help in the selection of pure and combined seas. See Souza (1988).

4.3. JONSWAP AND MITSUYASU RELATIONSHIPS

Several nondimensional parameters are used in the data modelling:

$$\tilde{f}_m = f_m U_{10}/g = \text{non dimensional peak frequency}$$

$$\tilde{E} = E g^2/4 ; \tilde{F} = F g/U_{10}^2$$

where F is the fetch, E the energy of the spectrum, f_m the peak frequency and U_{10} the wind at 10 mts.

Hasselmann proposed (1976) the following relationships between these parameters:

$$\tilde{f}_m = 2.84 \times \tilde{F}^{-0.3} \quad [5]$$

$$\alpha = 6.62 \times 10^{-2} \tilde{F}^{-0.2} \quad [6] \quad \alpha = 3.3 \times 10^{-2} \tilde{f}_m^{2/3} \quad [7]$$

$$\tilde{E} = 5.3 \times 10^{-6} \tilde{f}_m^{-10/3} \quad [8]$$

Mitsuyasu (1980) after experiments in bays and lakes suggested:

$$gE^{1/2}/u_*^2 = 1.31 \times 10^{-2} (gF/u_*^2)^{0.5} \quad \text{and}$$

$$f_m u_*/g = (g F/u_*^2)^2$$

where u_* is the friction wind

Using $u_* = CD U_{10}$ and CD , the drag coefficient, as 1.6×10^{-3} he arrived to the following relationships:

$$\tilde{E}^{1/2} = 5.24 \times 10^{-4} \tilde{F}^{1/2} \quad [9] \quad \tilde{f}_m = 2.92 \times \tilde{F}^{-1/3} \quad [10]$$

$$\tilde{E} = 6.84 \times 10^{-6} \tilde{f}_m^{-3} \quad [11]$$

The dimensional form of [11] is $E f_m^3 = 6.84 \times 10^{-6} g u_e^2$. Using E and f from the data an effective wind (U_e) can be calculated for the area. Differences between the two formulations can be explained by the use of different values for CD (J uses 1.0×10^{-3}).

4.4. THE TOBA MOEEL

The wind was measured at 40 mts. In order to improve the wind values and have more confidence when using the relationships for the nondimensional parameters, we used the model proposed by Toba (1978) for the high frequency part of the spectrum, to calculate u_* and U_{10} . The formulation is:

$$S(f) = \alpha' (2\pi)^{-3} g u_* f^{-4} \quad \text{for } f > f_m \quad [12]$$

$$\alpha' = 8.7 \times 10^{-2} \quad (\text{value suggested by Mitsuyasu (1980)})$$

u_* is calculated from:

$$u_* = (0.8 f_m)^{-1} \int_{1.2 f_m}^{2 f_m} (\alpha' g)^{-1} S(f) (2\pi)^3 f^4 df \quad [13]$$

From u_* we calculate U_{10} using $u_* = CD U_{10}$. For the calculation of CD we used the formula proposed by Garratt (1977) based in another one by Charnock adapted for an interval for U between 4 and 21 m/s.

$$CO \times 10^{-3} = 0.75 + 0.067 u_* \quad [14]$$

We can correct U_{10} to 40 meters by:

$$U_{40} = U_{10} (1 + (1/0.4) \sqrt{CO} \ln(40/10)) \quad [15]$$

and compare with the measured wind V_{40}

5. RESULTS AND DISCUSSIONS

5.1. CALCULATED PARAMETERS

The following parameters were calculated for each record: f_m (peak frequency), E (energy) H_s (- significant wave), u_* , $f_m^* = f_m u_*/g$, f_m , $E^* = E g / u_*$, F , U_{10} - wind at 10m from u_* , CO , V_{10} - measured wind reduced to 10m, α' , α and.

5.2. WIND CALCULATIONS AND COMPARISONS

For sea states free of swell, produced by local winds over small fetches it was possible to compare the wind at 10m calculated from u_* (U_{10}) with the wind at the same height (V_{10}) reduced from the wind measured at 40m (V_{40}). Table 1 below shows values of U_{10} , V_{10} , U_e and CO for situations of local winds and small fetches. The agreement is considered good, the differences being due to innacurate values of CO , innadequacy of the correction formula or even poor quality wind measurements.

Figure 7. F_m^* vs F

Using relation [11] from Mitsuyasu we can evaluate the quality of the u^* values as shown in fig.7 above. The data points refer to situations without swell.

5.3 - COMPARISONS OF α with f_m and \tilde{F}

Fig. 8 shows plots of α vs f_m , α vs \tilde{F} and γ vs \tilde{F} for the selected situations. The basic criterium for this selection is α' close to α_h

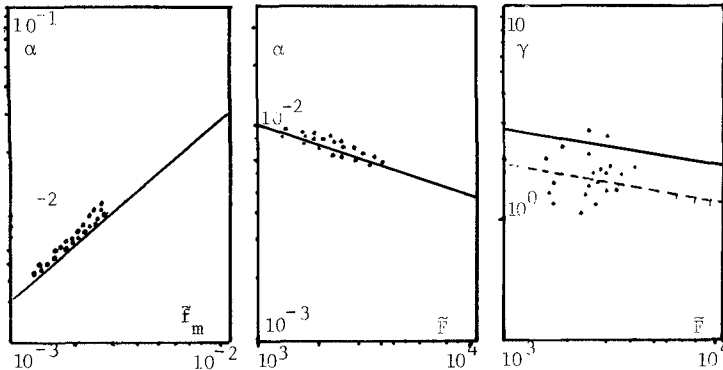

Figure 8. Comparison between parameters

5.4. CRITERIA FOR SELECTION OF SEA STATES

The following criteria were used to identify the different sea states in the area:

- a) fetch limited seas: high values of u^* , f_m^* and α_h ; α_h close to α' .
- b) developed seas: $f_m < 0.13$; u^* values indicating local sea and sufficient wind duration.
- c) swell (unimodal): no local wind; low values of f_m^* , α_h and α'
- d) fetch limited sea and swell: $\alpha' \gg \alpha_h$; high values of f_m^* .

5.5. ENERGY DISTRIBUTION

Using visual observations and establishing several criteria to separate different combinations of sea and swell it was possible to calculate a daily average of energy distribution per 22.5 degrees sector for every month. A computer program was written to compare values of α' and α_h and with this information and taking into account the peak frequency value to verify the quality of the visual observations and also the make a partition of the energy between the sectors. Table 2 below show this result.

6. CONCLUSIONS

The techniques presented in this work made possible to characterize the main features of the wave climate in the Campos basin based on wave data from point measurements.

The comparison of α_h and α' and the calculation of U_{10} from u_* produced good results and made possible an automatic identification of different sea states.

The South Atlantic anticyclone has an strong influence in the wave climate of the basin. The good weather prevails most of the time with NE winds and a combination of velocity and fetch in such a way that peak periods are always less than 7.5 seconds.

When the cold front is approaching the intensification of the NE wind is associated with small fetches so that again the peak period remains under 7.5 seconds.

The cold front bring strong SW winds and large fetches producing rough seas and peak periods between 11 and 15 seconds. When the front passes can produce SE winds with moderate fetches. A swell from SE occurs very often with

the NE wind blowing again and closing the cycle.

CHAPTER 18

AN EXPERIMENTAL STUDY OF HARBOUR RESONANCE PHENOMENA

F.M.Martinez *
V.S.Naverac **

An extensive series of experiments has been carried out at the laboratory in order to study rectangular harbour oscillation excited by incident long waves. Attention is focused on the effect of head loss entrance on resonant response attenuation. A "gross" quadratic hydraulic head loss coefficient is defined and information about it, resulting from tests, is provided. Experimental conditions used in this piece of work seem to be realistic under suitable scaling for Northern Spain harbours.

Introduction

It is a well known fact that long period waves induce harbour oscillations and can cause severe problems to moored ships: breakage of mooring lines, hazards in berthing and cargo handling and possibly an eventual leaving of the berth, damaged fenders and so on.

Resonance of harbours has attracted the attention of researchers and has been successfully studied by means of both mathematical and physical models including the cases of inviscid and real fluid. If real fluid effects are ignored a narrowing of the harbour entrance leads to an enhancement in harbour surging ("harbour paradox", Miles and Munk (1961)).

Previous studies have shown the importance of frictional loss at the harbour entrance (Fukuuchi and Ito (1966), Ito (1970), Horikawa and Nishimura (1970), etc) and the effectiveness of energy dissipation due to friction at the bottom, Kostense et al (1986), in order to influence the peak amplitude, particularly at the first mode of resonance.

This piece of work, where abstraction is made about the long wave origin, includes results, analysis and comparison of different test carried out at the laboratory on two rectangular harbour models excited by incident regular long waves. Attention is focused on

* Director

Antonio López, 81, 28026 Madrid, SPAIN

definition, evaluation and providing some information about a quadratic hydraulic "gross" head loss coefficient by using, under some special experimental conditions, a significant reference velocity.

Although numerical models predict the natural frequencies and the corresponding oscillation modes there is an increasing need for realistic values of amplitudes and as a consequence more experimental information is also needed about head loss or friction coefficient values.

Other previous experimental works (Horikawa and Ishimura (1970), Lee (1971), Lee and Raichlen (1972), Giles and Lee (1975), etc.) considered the case of a total reflective coast. In this study, the imposed conditions ignore the reflected waves from the coast in the same way as a harbour with breakwaters protruding seaward from a dissipative beach. This hypothesis was used by Iribarren (1958) studying the resonance phenomena in the Spanish Basque Country harbours.

Although the first mode of resonance has only been tested the proposed "gross" coefficient could be relied on to apply to Helmholtz or pumping mode.

Lee (1971) and (1972) provides a comprehensive summary about experimental research in this field.

Some experimental works aimed at solving real problems have been carried out by different researchers: Wegell and Sorensen (1980), etc.

Remarks about the theory

a) Effect of a sudden constriction. Usual approach.

From continuity, energy and momentum equations applied between two sections at each side of a sudden constriction, outside the eddy zone, we may write:

$$\Delta\eta = \frac{k}{2g} u|u| + \frac{L}{g} \frac{\partial u}{\partial t} \quad (1)$$

Mei (1983), where

$\Delta\eta$ = free surface elevation difference
 u = velocity
 k = head loss coefficient
 L = length coefficient

If apparent inertia term is neglected equation (1) becomes:

$$\Delta\eta = \frac{k}{2g} u|u| \quad (2)$$

The quadratic friction term makes the problem non linear and the so-called equivalent linearization may be applied if the response is dominated by the first harmonic:

$$\Delta \eta = C u \quad (3)$$

$C =$ equivalent friction coefficient

Ito (1970) and Horikawa and Nishimura (1970) developed a theoretical model which incorporated formula (2) by using an estimated constant K proved to be reliable from Ofunato Bay results against tsunami.

b) Located head loss

In non-oscillatory flows the head loss at a sudden constriction may be written:

$$\Delta H = K \frac{V^2}{2g}$$

where

$\Delta H =$ head loss (specific energy difference)
 $V =$ reference velocity
 $K =$ coefficient attached to V

$K = K(\text{Re, geometry})$
 $\text{Re} =$ flow Reynolds number
 if the flow is highly turbulent
 $K = K(\text{geometry})$

In highly turbulent oscillatory flows:

$K = K(\text{geometry, oscillatory, Strouhal or Keulegan - Carpenter, etc., flow numbers})$

Proposed analysis

The present analysis, aimed at yielding reasonable global predictions, is rather different from the usual ones and can be formulated as following:

Assuming that ΔH is the water surface elevation difference, with and without constriction at the entrance, at the back wall section inside the rectangular harbour, we may write:

$$\Delta H = K \frac{V^2}{2g} \quad (5)$$

under the hypothesis that head loss balances at the harbour entrance the joint effect of surface elevation, radiation and reflection difference. Measuring ΔH and taking an appropriate and significant reference velocity V , a "gross" quadratic head loss coefficient K , can be estimated, which is indicative of constriction effectiveness and useful to practical applications.

- K estimation

Let : a = the outside amplitude (a=h/2; h=long wave height)
 f_0 = the amplification factor at resonance without constriction
 f_i = the amplification factor at resonance with constriction i

The amplification factor is defined as the ratio of the maximum wave height occurring in the harbour model to the wave height measured outside. For the first mode of resonance, the maximum wave height occurred along the back wall of the model. (f_0 and f_i are referred to maximum amplitude inside the harbour).

Thus: $\Delta H = f_0 a - f_i a = (f_0 - f_i) a$

putting $v = \sqrt{2gf_i a}$ (from Bernouilli/Torricelli law)

and invoking (6), we have:

$$K = \frac{f_0}{f_i} - 1$$

Bearing in mind that the amplification factor is a function of amplitude and other variables.

The effectiveness of constriction can also be simply evaluated by means of:

$$E = \frac{(f_0 - f_i)^a}{f_0^a} = 1 - \frac{f_i}{f_0} = 1 - \frac{1}{K} \quad (8)$$

Experimental apparatus

A series of experiments, aimed at f and K evaluation, was conducted at the laboratory in a rectangular wave basin 0.5 m deep, 5 m. wide and 18 m. long. The hydraulic piston wave generator was located at one end of the basin.

Fig. 1.- Wave basin. Plan view

A 5:1000 beach was built opposite the wavemaker in order to minimize wave reflections. Regular waves were generated with amplitudes (height) between 3 and 8 mm. and frequencies in the range 0.150-0,05 Hz. Two rectangular harbour models were used:

- Model A (2m. long, 1m. wide, 0.1m. deep)
- Model B (2m. long, 0.5 m. wide, 0.1m. deep)

Constrictions at the model entrance were made by using sharp edge elements as breakwaters. Effective wave absorbers (coconut fiber blankets and metallic wire filters) were placed to minimize reflections. Water surface levels were recorded, inside and outside the harbour basin model, when resonance had reached stationary conditions, by using resistive gauges placed to provide information about different conditions (open sea without model, standing waves, partially reflected waves, etc.).

Flow Reynolds number values guaranteed turbulence development in the models. Long wave requirements were fulfilled.

Extrapolation to real conditions is assumed to be made by using Froude similarity, without or with slight scale distortion

Results and analysis

Figures 2 to 5, similar to those of other authors, summarize some results corresponding to the present experiments in the case of centered entrance.

Fig. 2.- f versus T curves. Model A. Pure wave 4mm.

The amplification factor versus period bell-shaped curves, corresponding to several opening ratios, show clearly the peak response attenuation, inside the harbour, due to entrance friction. Separation of horizontal flows at each end of the entrance was very noticeable in the experimental work.

Fig. 3.- f versus T curves. Model A. Pure wave 6mm.

Amplification factor and resonant period depend upon the opening ratio, on harbour and entrance geometries and on oscillatory flow characteristics.

Bell-shaped curve "steepness" depends on the outside amplitude and on the harbour geometry. Small outside amplitudes lead to an increase in curve "steepness", larger ones lead to smoother curves. Note that increasing the amplitude leads to a decrease in f .

In the range of present experimental conditions, nearly fifty percent of peak amplitude reduction inside the harbour can be achieved with fifty percent of entrance aperture ratio.

As was previously pointed out, amplification factor depends upon the harbour geometry. Increasing the harbour ratio (width/length) leads to a decrease in amplification factor and viceversa.

From test results it can be concluded that the reduction of resonant peaks by entrance loss is more pronounced for larger amplitude and narrower entrance.

Fig. 4.- f versus T curves. Model B. Pure wave 7 mm.

Fig. 5.- f versus T curves. Model B. Pure wave 8mm.

The observed displacement of resonance peak period as a consequence of entrance constriction enables us to find out that it is important to take into account the range of frequencies where head loss is effective, otherwise some kind of harbour paradox may result.

From test data, "gross" head loss coefficient values were estimated by using (6).

Figure 6 shows K values versus opening ratio curves, corresponding to two outside amplitudes considered to be appropriated for Cantábrico sea conditions.

Fig.-6 K versus aperture ratio curves.

With present experiment results, the "gross" head loss coefficient K proved to be practically independent of harbour geometry, (Width/length) ratio; K strongly depended on the outside amplitude.

In general, K may depend, for highly turbulent flows, on the Strouhal, or Keulegan - Carpenter, number and on geometry of breakwater-tips, not considered in this piece of work.

Fig. 7 correlates amplification factor values under different hypothesis related to measured outside amplitude: open sea or pure wave (basin without harbour model), partially reflected and radiated wave and standing wave with harbour entrance blocked off.

Fig. 7.- f correlations.

From test data, calculations were made in order to evaluate the harbour effective length: distance from the harbour back wall to node of the standing wave near the harbour mouth. Comparison with theoretical length resulting from asymptotic formulas, for the fundamental mode, enables us to point out that lower opening ratios require severe modifications of f_3 , Miles and Munk (1961), function, adequate for inviscid fluid conditions or hypothesis. Asymptotic formula overestimates effective length for lower apertures. A linear approximation fits rather well with test results.

Summary and conclusions

Experiments were conducted at the laboratory in order to measure the importance and effectiveness of friction loss at the harbour entrance. Two rectangular harbour models with several opening ratios were used.

Entrance head loss practically eliminates the first mode (quarter wave mode) of resonance as was pointed out earlier.

A "gross" head loss coefficient K , including the joint effect of reflection, transmission, radiation and friction differences, is defined and evaluated under some special experimental conditions by using a significant reference velocity.

Curves amplification factor versus period or equivalent magnitude, deduced from tests, have shown that it is important to take into account the range or periods where constriction is effective, if not undesirable "harbour paradox" effects may result.

K values, under different assumptions are provided.

K values and bell-shaped curves (f versus T) have shown to be dependent on oscillatory flow characteristics. The influence of oscillatory numbers needs to be investigated.

Basin dimensions, water depth, long wave characteristics and other experimental conditions could be extrapolated to harbours in Northern Spain by using suitable scales.

Research was limited to first mode of resonance; analysis carried out seems to be appropriate to Helmholtz or pumping mode.

f_3 , Miles and Munk (1961) function, overestimates effective length for severe constrictions where real fluid effects are important.

CHAPTER 19

Development and Application of a Mathematical Model of Wave Action on Steep Slopes

N W H Allsop*
J V Smallman@
R V Stephens+

Abstract

This paper summaries the initial stages in the development of a mathematical model of wave action on slopes. The model calculates water surface elevation and depth averaged velocity on the slope, and uses this data to estimate the level of wave run-up. The model has been validated by comparing its results with those from similar models, and from a physical model. Examples are presented of these comparisons, which were found to be in good agreement in most cases.

1 Introduction

A mathematical model has been developed to estimate wave induced flows on sloping faces of breakwaters, coastal revetments and seawalls. Of particular interest is the application of the model to slopes armoured with high porosity single layer armour units. The model calculates instantaneous surface elevations and uprush/downrush velocities for waves normally incident to a slope. The nature of the armour layer is described in terms of an empirical roughness coefficient which must be calibrated against flume measurements and, if possible, also against prototype measurements. Part of a field measurement programme on a breakwater in Jersey has recently been completed, see Stephens (1988), and it is anticipated that its results will be used to calibrate the mathematical model in the near future.

The mathematical model once calibrated will be of value in preliminary assessment of hydraulic characteristics of an armoured slope. It is envisaged that one of its applications will be in examining various options prior to more extensive physical model testing. The use of this numerical model, together with physical modelling techniques, may lead to considerable improvements in efficiency and cost over the alternative of simply testing a number of potential designs in a physical model.

2 Description of the mathematical model

The basic technique used in the mathematical model is to solve numerically the non-linear shallow water wave equations. Boundary conditions allow reflection and run-up at a steep slope to be incorporated. The set of equations which are solved contain a term to describe frictional dissipation on a rough slope. The model is based on a method originally developed for beach slopes which is reported in Hibbard & Peregrine (1970) and Packwood & Peregrine (1981). Clearly many structural slopes will be considerably steeper than typical beach slopes, and the extension of the original method to include steeper slopes has been described by Kobayashi et al (1987) and is also addressed in a companion paper by Thompson (1988).

The layout and co-ordinate system used in the mathematical model are shown in Figure 1. It should be noted that the x' co-ordinate is taken to be positive in the landward direction, with $x' = 0$ at the toe of the slope. The z' co-ordinate is taken to be positive upwards with $z' = 0$ at the toe of the slope. The water depth is denoted by h' and the depth averaged velocity by u' . The local angle of the slope is θ' . The structure slope, s' is defined by $\frac{ds'}{dx'} = \theta'$. The slope is assumed horizontal for $x' < 0$.

Incident wave amplitude a' , period T'

Figure 1 Mathematical model layout

The incident wave train is specified at the toe of the slope, where the water depth below SWL is given by h_0 . It is assumed that the slope is impermeable, waves are non-breaking and that no overtopping occurs. Vertical pressure is taken to be hydrostatic and the vertical fluid acceleration is assumed to be negligible. This is a reasonable assumption for a relatively mild slope, i.e. $\tan \theta' \ll 1$.

The governing equations may then be expressed in dimensionless form as:-

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x} (hu) = 0 \quad (1)$$

$$\frac{\partial}{\partial t} (hu) + \frac{\partial}{\partial x} (hu^2 + \frac{1}{2}h^2) = -\theta h - f|u|u \quad (2)$$

where

$$h = h'/a', \quad u = u'/(ga')^{\frac{1}{2}}$$

$$t = t'/T', \quad x = x'/T'(ga')^{\frac{1}{2}},$$

$$\theta = T'(g/a')^{\frac{1}{2}} \tan \theta' \quad \text{and} \quad f = \frac{1}{2}T'(g/a')^{\frac{1}{2}}f'.$$

here f' is an empirically determined constant friction factor associated with the slope, a' is the incident wave amplitude and T' is the incident wave period. For all the mathematical model tests described in this paper the incident wave train is taken to be sinusoidal.

In addition to the governing equations, initial and boundary conditions also need to be specified. At time $t = 0$ the fluid is assumed undisturbed giving initial conditions

$$h = h_0 - s, \quad u = 0 \quad \text{at} \quad t = 0, \quad x > 0$$

The seaward boundary condition is derived from a characteristics based argument in which it is assumed that waves reflected from the structure do not modify the incident wave. The derivation of the seaward boundary condition used in the model is described in Reardsley et al (1988). At the landward boundary it is assumed that both the water depth on the slope and its velocity are zero at the leading edge of the wave.

The governing equations (1) and (2) are presently solved using a Lax Wendroff finite difference scheme. This has the advantage of being relatively easy to apply, and is numerically stable provided the Courant condition,

$$(gh_0)^{\frac{1}{2}} \frac{\Delta t}{\Delta x} < 1 \quad ,$$

where Δt and Δx are the time and space steps, is satisfied. This scheme has been found to provide a reasonably efficient and robust method for solving the differential equations for waves of moderate steepness. For steeper waves there will be inaccuracies introduced by using this finite difference scheme, and the adoption of an alternative method will be necessary. The alternatives which have been examined so far are all Roe type schemes, see Priestley (1987), which are widely used in aerodynamic problems. The results from early

tests with these schemes appear promising, and work is currently underway to investigate them further.

3 Calibration and validation of the mathematical model

Similar mathematical models to the one described here have been developed by both Kobayashi et al (1987) and Thompson (1988). Therefore a starting point in validating the model is to compare its results with those available from similar models. In addition, a series of physical model tests were carried out at Hydraulics Research to allow comparisons to be made between the mathematical model results and those from a physical model.

3.1 Comparisons with other mathematical models

On comparing the results from the present model with those of Thompson very good agreement was achieved both for the surface elevations and velocities calculated by the model. In general the differences between the two sets of model results was less than 5%. The outcome of these comparisons is discussed further in Beardsley et al (1988).

The results from the present model were also compared with one of the cases given in Kobayashi et al (1987). Both models use a similar form of the equations and boundary conditions, and the same finite difference scheme. The only significant difference between them will be in the numerical implementation and the accuracy of the computer on which the models are run.

The present model was run for the case $\theta = 6.0$, $h_0 = 5.8$, $\sigma \equiv T' \left(\frac{g}{h} \right)^{1/2} = 15$ and $Ur = 4.5$. It should be noted that these are all dimensionless variables, and that therefore the results are also given in terms of dimensionless values h and u . In fact the angle θ given here is equivalent to a slope of 1:2.5. The results from the two model tests are compared in Figures 2 and 3 in terms of the dimensionless elevations and velocity. The present model was run using a dimensionless time step $\Delta t = 0.0025$ and dimensionless space step $\Delta x = 0.01$; these satisfy the stability constraint. The results were plotted after 5, 5.25, 5.5 and 5.75 wave periods had elapsed.

It can be seen that the predicted elevations between the two models are in close agreement, but that in general Kobayashi's model gives velocities which are higher in magnitude. This discrepancy is probably due to the different time steps which were used in running the models. Kobayashi uses 2000 time steps per wave period whereas in the present model a maximum of 400 per wave period were used. Some early runs of the present model were actually made with 250 time steps per wave period and increasing to 400 was found to have no significant effect on the velocity profiles. It is therefore likely that the discrepancies can only be due to machine rounding errors, which will have a small but cumulative effect on the solution.

3.2 Comparison with physical models

Tests were conducted in the 'Deep Wave Flume' facility at Hydraulics Research. A smooth impermeable slope was constructed at a gradient of 1:2. The flume bed profile seaward of the test slope was at a gradient of 1:50. In all of the tests the static water level was

Figure 2 Comparison of model elevation with those of Kobayashi

Figure 3 Comparison of model velocities with those of Kobayashi

set to be 0.3 metres above the toe of the 1:2 slope. A series of parallel vertical wave probes were positioned at regular intervals up the slope (see Fig 4) to measure instantaneous surface elevation. Measurements were also made of wave run-up and reflection, and the tests were recorded using a video camera.

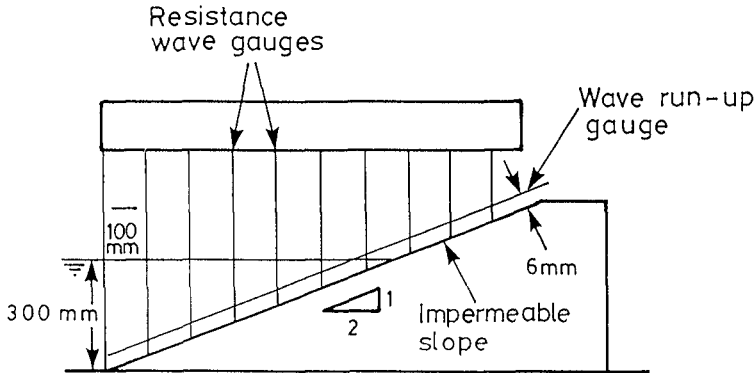

Figure 4 Layout for physical model tests

Two sets of tests were run; the first for the smooth, impermeable slope; and the second for the same slope covered with a single layer of Shed armour units. In each instance, short sequences of regular waves were run for a variety of combinations of wave height and period. The philosophy behind running these tests was that they should be used to provide calibration data for the mathematical model.

To run the mathematical model a friction factor f' needs to be specified. For this model f' is regarded as a calibration factor which needs to be determined experimentally. Once a value of f' has been determined for the particular slope characteristics, it would then be used for all subsequent tests with slopes of that type.

As a starting point in the calibration the mathematical model was set up to represent the experimental layout. The first case to be examined used a wave amplitude of 0.043m and a wave period of 2.0s at the seaward boundary. These incident conditions were taken from the results of a reflection analysis performed in the physical model at an equivalent position. The model was run using a time step of 0.0075s and a space increment of 0.018m; these satisfy the stability constraint.

For this first case a variety of friction factors were used in the mathematical model. After each run a visual comparison of the

Figure 5 Comparison of elevations for physical and numerical models

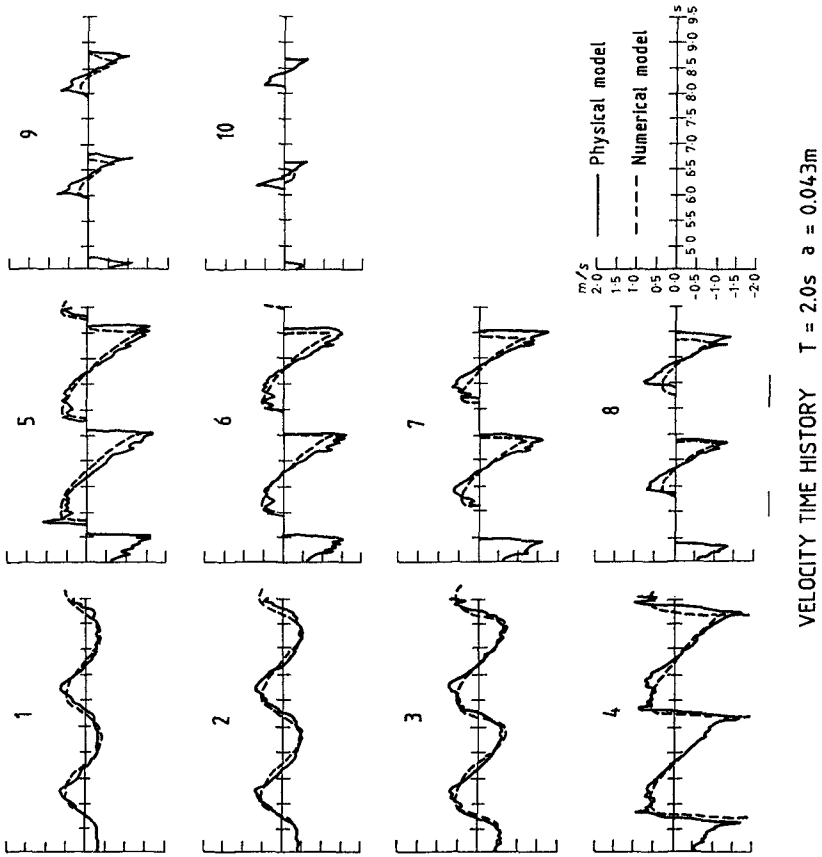

Figure 6 Comparison of velocities for physical and numerical models

elevation and velocity time histories at positions corresponding to the location of the wave probes in the physical model were made. Good agreement was achieved using a friction factor of 0.01. The comparisons for this case are shown in Figures 5 and 6, where results are plotted for each of the probe positions shown in Figure 4. It can be seen from Figure 5 that the elevations predicted by the mathematical model are in good agreement with those from the physical model. The agreement between the velocities (Figure 6) is not as good as for the elevations, but is reasonable with the same specific trends being displayed.

The next stage in the calibration process is to make similar comparisons for other wave conditions which were tested in the physical model. However, rather than relying on a visual comparison to assess the best choice of friction factor, the maximum run-up levels and velocities at probe positions will be examined. Analysis of results obtained using this method is still in progress, but they appear to be promising, and give confidence that the mathematical model can be developed and used further to represent wave action on rough slopes.

4 Conclusions

The non-linear shallow water equations have been adapted to calculate wave action on steep slopes. A number of numerical techniques have been investigated, and initial comparisons made with physical model tests. The results from the mathematical model appear to give a reasonable representation of the hydrodynamic processes. Clearly, further research is needed to develop the model and extend and improve its range of applicability. However, the results reported here indicate that the model will eventually be a useful tool for the engineer involved in the design of coastal structures.

5 Acknowledgements

The work described in this paper forms part of the research carried out for the Single Layer Armour Unit Research Club in the Maritime Engineering Department of Hydraulics Research. The authors would like to thank Mr Andrew Beardsley and Mr Barry Edwards of Brunel University for their assistance.

CHAPTER 20

ABOUT THE ENERGY DISSIPATION OVER BARRED BEACHES

by

Johannes Oelerich 1) and Hans-Henning Dette 2)

Abstract:

Since wave energy dissipation in the surf zone is a stochastic process closed mathematical formulations cannot be expected. The dissipation was computed using several analytical and/or empirical approaches and compared with prototype measurements in the Big Wave Flume (GWK) in Hannover as well as with field measurements from the west coast of the Island of Sylt/North Sea. Generally good agreements were found for moderate energy dissipation conditions (spilling-breaker), whereas in the case of plunging breakers, however, the fitting is not solved satisfactory.

1. Introduction

Due to the stochastic nature of energy dissipation in the surf zone, closed mathematical solutions for the given sea state in the nearshore zone cannot be expected. It is therefore the task to idealize the problem and/or to apply empirical approaches based on laboratory- and/or in-situ measurements of waves in the area of interest.

Laboratory investigations were carried out in the Big Wave Flume (GWK) and in-situ measurements at the Island of Sylt in order to obtain data representing spilling- and plunging breaker conditions for comparison with the results from selected decay models.

2.1 Empirical Wave Height Decay Formulations

Two empirical approaches have been selected for computational tests. HORIKAWA/KUO(1966) derived from laboratory tests the following formulation for the determination of wave height decay:

1) research engineer 2) senior research engineer

Leichtweiß-Institut für Wasserbau, Department of Coastal Engineering, Technical University of Braunschweig, Beethovenstr. 51a, 3300 Braunschweig, West-Germany

$$\frac{H_i}{d_i} = 0.5 + 0.3 \cdot \exp\left(-0.11 \cdot \frac{x_i}{m \cdot x_b}\right) \quad (1)$$

H_i = wave height at x_i in [m]
 d_i = water depth [m]
 x_i = distance shoreward from break-point [m]
 i = arbitrary location index
 x_b = distance of shoreline to break-point [m]

This approach was modified by ANDERSON/FREDSØE(1983) for plane slopes. The coefficients were adapted to spilling-breakers as they do occur along the westcoast of Jütland/-Denmark:

$$\frac{H_i}{d_i} = 0.35 + 0.65 \cdot \exp\left(-0.12 \cdot \frac{x_i}{H_b}\right) \quad (2)$$

H_b = wave height at the break-point [m]

In case of partial wave breaking over a bar TUCKER et al.(1983) found that waves restabilize themselves at:

$$\frac{H_i}{d_i} = 0.5 \quad (3)$$

2.2 Analytical Wave Height Decay Formulations

Three analytical approaches were applied for describing wave height decay of periodic waves. DALLY et al.(1984) have developed an approach based on energy conservation law:

$$\frac{H_i}{H_b} = \left[\left(\frac{h_i}{h_b} \right)^{\left(\frac{K}{m_i} - 0.5 \right)} \cdot \left(1 - \alpha_i \right) - \alpha_i \cdot \left(\frac{h_i}{h_b} \right)^2 \right]^{0.5} \quad (4)$$

$$\alpha_i = \frac{(K \cdot \Upsilon)^2}{m_i \cdot \left(2.5 - \frac{K}{m_i} \right)} \cdot \left(\frac{h_b}{H_b} \right)^2$$

h_i = water depth at still water level [m]
 h_b = still water level at the breakpoint [m]
 m_i = beach slope at location x_i [-]
 K = waveheight decay factor [-]
 Υ = waveheight stabilization factor [-]

BATTJES(1986) published an approach based on the analogy of energy dissipation of a spilling breaker to the energy dissipation in a bore:

$$\frac{H_i}{H_b} = \left[\left(1 - \frac{4}{9} \cdot k \right) \cdot \left(\frac{d_i}{d_b} \right) + \frac{4}{9} \cdot \left(\frac{d_i}{d_b} \right)^{-3.5} \right]^{-0.25} \quad (5)$$

$$k = 2 \cdot B \cdot \Upsilon \cdot \frac{1}{m_i \cdot T_m} \cdot \left(\frac{d_b}{g} \right)^{0.5}$$

$$\gamma = 0.7 + 5 \cdot m_i \quad (0.01 \leq m_i \leq 0.1)$$

B = dimensionless coefficient [-]
 d_b = water depth at the breakpoint [m]
 T_m = mean wave period [s]

STIVE (1984) derived a formula based on the same analogy but added an energy dissipation factor A_e for better adaptation:

$$\frac{H_i}{H_b} = \left[\left(1 - \frac{4}{3} \cdot \sigma \right) \cdot \left(\frac{d_i}{d_b} \right)^{0.25} + \sigma \cdot \frac{4}{3} \cdot \left(\frac{d_i}{d_b} \right)^{0.5} \right]^{-1} \quad (6)$$

$$\sigma = \left(\frac{1}{2 \cdot \pi} \cdot \frac{H_b}{d_b} \right)^{0.5} \cdot A_e \cdot \zeta_b^{-1} \quad \zeta_b = m_b \cdot \left(\frac{H_b}{L_o} \right)^{-0.5} \leq 0.4$$

$$A_e = 2 \cdot \tanh(5 \cdot \zeta_o) \quad \zeta_o = m_b \cdot \left(\frac{H_o}{L_o} \right)^{-0.5} \leq 0.5$$

H_o = deep water wave height [m]
 L_o = deep water wave length [m]
 m_b = bottom slope at the break-point [-]

Another five approaches have been selected to take as well wave height distribution as water level set-up/set-down into account.

Based on linear wave theory wave height is calculated:

$$\frac{H_i}{H_o} = \left[\frac{1 + \frac{4\pi d_o}{L_o}}{\sinh\left(\frac{4\pi d_o}{L_o}\right)} \cdot \frac{2\pi}{L_i} \right]^{0.5} \cdot \frac{\sinh\left(\frac{4\pi d_i}{L_i}\right) + \frac{4\pi d_i}{L_i}}{\sinh\left(\frac{4\pi d_i}{L_i}\right)} \cdot \frac{2\pi}{L_o} \quad (7)$$

set-up/set-down offshore the break-point:

$$\eta_i = -\frac{1}{8} \cdot H_o^2 \cdot \frac{2\pi}{L_o} \cdot \frac{\coth^2\left(\frac{4\pi d_i}{L_i}\right)}{\sinh\left(\frac{4\pi d_i}{L_i}\right) + \frac{4\pi d_i}{L_i}} \quad (8)$$

set-up/set-down inside the breaker-zone:

$$\eta_i = \frac{3 \cdot \gamma_b^2}{3 + 3 \cdot \gamma_b^2} \cdot (h_b - h_i) + \eta_b \quad (9)$$

$$\gamma_b = \frac{H_b}{d_b} = 0.78$$

η_i = deviation from still water level (set-up/set-down) [m]
 η_b = set-up/set-down at the breakpoint [m]

L_i = wave length [m]

Wave height decay formulations of DALLY et. al. (1984) are mentioned above. The set-up/set-down is calculated by:

$$\eta_i = \eta_{i-1} - \frac{3}{16} \cdot \frac{1}{d_i} \cdot (H_i^2 - H_{i-1}^2) \quad (10)$$

At barred coastlines waves restabilizes at:

$$\frac{H}{d} = \alpha \quad (11)$$

$\alpha = 0.35$ - moderate beach slopes

$\alpha = 0.48$ - steep beach slopes

IZUMIYA/HORIKAWA (1978) calculated wave height and wave set-up/set-down from energy dissipation rate due to wave breaking and bottom friction. There expressions are:

$$H_i = \left(\frac{8 \cdot E_i}{\rho \cdot g} \right)^{0.5} \quad (12)$$

$$E_i = E_{i-1} \cdot \frac{C_{gi-1}}{C_{gi}} - \frac{X_i - X_{i-1}}{C_{gi}} \cdot \left[\alpha_1 \cdot \left(\frac{2k_i d_i}{\sinh(2k_i d_i)} \right)^{1.5} + \alpha_2 \cdot \left[\left[\frac{E_i}{\rho \cdot g \cdot d_i} \cdot \left(\frac{1}{2} + \frac{k_i d_i}{\sinh(2k_i d_i)} \right) - \alpha_3 \right]^{0.5} \cdot \left(\frac{2k_i d_i}{\sinh(2k_i d_i)} \right)^{0.5} \right] \right] \cdot \frac{E_i^{1.5}}{\rho^{0.5} \cdot d_i^{1.5}}$$

$$k_i = \frac{4 \cdot \pi^2}{T_m^2 \cdot g \cdot \tanh(k_i \cdot d_i)}$$

$$C_{gi} = \frac{1}{2} \cdot \left[\frac{g}{\frac{2\pi d_i}{L_i}} \cdot \tanh\left(\frac{2\pi d_i}{L_i}\right) \right] \cdot \left[\frac{1 + \frac{2\pi d_i}{L_i}}{\sinh\left(\frac{2\pi d_i}{L_i}\right)} \right]$$

E_i = wave energy [kWs/m²]

$c_{g i}$ = group velocity [m/s]

k_i = wave number $2\pi/L$ [-]

α_1 = bottom roughness coefficient = 0.01 - 0.03

α_2 = wave breaking coefficient = 10

α_3 = wave breaking coefficient = $0.9 \cdot 10^{-2}$

The water level deviation is calculated based on radiation stress theory:

$$\eta_i = \eta_{i-1} - \frac{S_{xxi} - S_{xxi-1}}{\rho \cdot g \cdot d_i} \quad (13)$$

$$S_{xxi} = \left(\frac{1}{2} + \frac{2k_i d_i}{\sinh(2k_i d_i)} \right) \cdot E_i$$

S_{xxi} = radiation stress [kWs/m²]

The break-point is defined as a critical relative wave-height due to a critical energy:

$$\left(\frac{H}{d}\right)_{crit} = 0.17 \cdot \frac{L_o}{d} \cdot \left[1 - \exp \left[-1.5 \cdot \frac{\pi d}{L_o} \cdot (1 + 15 \cdot m)^{1.33} \right] \right] \quad (14)$$

BATTJES/JANSSEN (1978) calculated the energy dissipation rate for RALEIGH distributed waves:

$$H_{rmsi} = \left(\frac{8 \cdot E_i}{\rho \cdot g} \right)^{0.5} \quad (15)$$

$$E_i = E_{i-1} \cdot \frac{C_{gi-1}}{C_{gi}} - \frac{\alpha}{8} \cdot \frac{1}{T_m} \cdot \frac{0.88^2}{C_{gi}} \cdot \left[\frac{Q_{bi}}{k_i^2} \cdot \tanh^2(k_i \cdot d_i) + \frac{Q_{bi-1}}{k_{i-1}^2} \cdot \tanh^2(k_{i-1} \cdot d_{i-1}) \right] \cdot (x_i - x_{i-1})$$

$$\frac{1 - Q_{bi}}{\ln(Q_{bi})} = \frac{H_{rmsi}^2}{H_b^2}$$

H_{rmsi} = root-mean-square-wave-height [m]
 Q_{bi} = probability of broken- or breaking waves [-]
 α = 1.0

The wave set-up is calculated due to radiation stress theory mentioned above.

The approach of GERRITSEN (1980) is similar to BATTJES/-JANSSEN(1978) (eqn.15) but assumes the waves as WEILBULL distributed:

$$\frac{1 - Q_{bi}}{((1+0.71) \cdot (Q_{bi}-1)^2) \cdot \ln(Q_{bi})} = \frac{H_{rmsi}^2}{H_b^2}$$

The energy dissipation formula was modified for the WEILBULL distribution as follows:

$$E_i = E_{i-1} \cdot \frac{C_{gi-1}}{C_{gi}} - \left[\frac{2}{3} \cdot \alpha_1 \cdot \frac{\rho}{\pi} \cdot \left(\frac{\pi \cdot H_{rmsi}}{T_m \cdot \sinh(k_i d_i)} \right)^3 + Q_{bi} \cdot \frac{\alpha_2}{5.66} \cdot \rho \cdot g \cdot \frac{2\pi}{T_m} \cdot H_{rmsi}^2 \right] \cdot (x_i - x_{i-1}) \cdot C_{gi}$$

α_1 = bottom friction coefficient = 0.1 - 0.5
 α_2 = wave breaking coefficient = 0.1 - 0.36

The energy dissipation thus can be calculated in correspondence with the decay of wave height for different nearshore profiles and wave conditions.

3. Applications of Wave Height Decay on a natural Profile in Full Scale Experiments

In the Big Wave Flume (GWK) full scale experiments over natural beach profiles with sand ($D_{50} = 220 \mu m$) have been carried out under a wide range of wave-, beach- and profile conditions.

3.1 Wave Height Decay of individual Waves

The wave height decay from the breakpoint up to the uprush zone was recorded by means of video registrations of breaking wave trains through a grid at one of the tank walls and analysed for nearly 100 successive waves. The waves have been characterized by the breaker parameter β (FÜHRBÖTER(1976)) (see Fig. 2).

Fig. 1 shows the measured and computed wave height decay in the surf zone for a spilling breaker (above) and a plunging breaker (below).

The comparison of computed values with measured data is illustrated in Fig. 2. in terms of the difference in wave height ΔH and the standard deviation $\sigma(\Delta H)$. For DALLY et al. (1984) and BATTJES(1986) the parameters K , Γ , and B have been adapted to the individual wave heights in order to minimize the differences ΔH . Table 1 shows the results of the parameters as functions of H_b/d_b and breaker parameter β .

3.2 Energy Dissipation of irregular Wave Trains in Full-Scale Experiments

Dissipation of wave energy profile changes are caused until a morphologic equilibrium is reached. For investigations during such profile transformation processes the wave heights were measured by resistance wave gauges at 10 locations at intervals of 10 m along the beach profile for regular waves as well as irregular waves.

The results of statistical analysis are presented in Fig. 3. for each wave gauge as follows:

- deviation from SWL η (set-up/set-down)
- dimensionless probability density function $p(H/H_m)$
- statistical wave height parameters H_m , $H_{1/3}$, H_{max}

The results of spectral analysis are shown in Fig. 4 for each wave wire:

- spectral density function presented as block diagram
- spectral parameters H_s , $T_{m0,2}$, and band width parameter ν

The computed wave heights and set-up, respectively, of the models described in section 2. are plotted together with wave height parameter H_m and deviations for the initial wave parameters of the reference wave gauge and the actual profile from SWL as obtained from measured data (see Fig. 5).

Fig. 1: Comparison between measured data (GWK) and wave-height calculations by empirical and analytical wave decay models for a spilling breaker (above) and an extreme plunging breaker (below) at a natural profile.

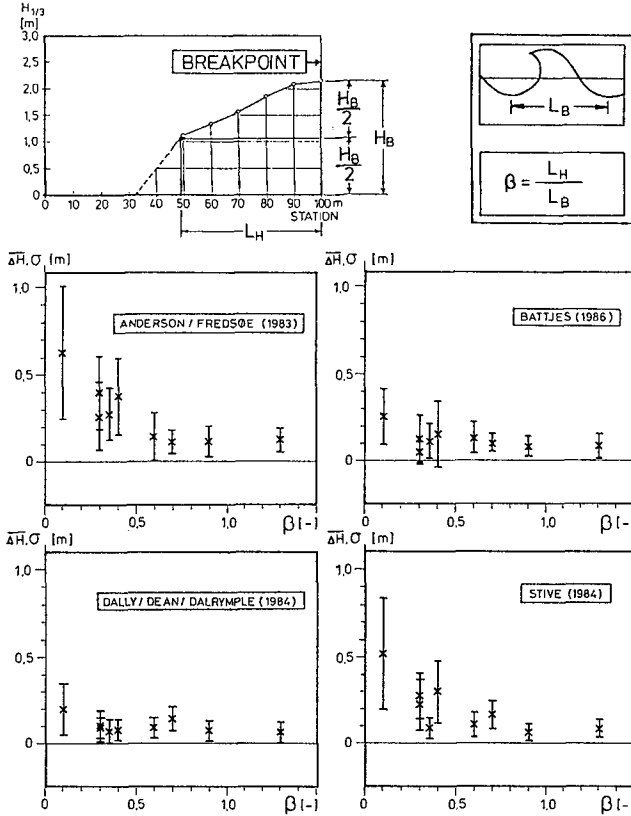

Fig. 2: Mean differences between measured and computed wave heights ΔH and standard deviations $\sigma(\Delta H)$ as function of the breaker parameter β .

INDIVIDUAL BREAKING WAVES		BIG WAVE FLUME HANNOVER			
Breaker-type	Wave-Parameter		Energy-Dissipation-Parameter		
	β [-]	H_b/d_b [-]	DALLY et. al. K [-]	BATTJES γ [-]	BATTJES B [-]
extreme plunging plunging spilling	0.1-0.2	1.4-1.8	0.5 -1.0	0.5	5.0-20.
	0.2-0.7	0.7-1.4	0.2 -0.3	0.35-0.5	1.0-10.
	0.7-1.4	0.7-1.1	0.2	0.35-0.5	1.0- 2.
	H_0/gT^2 [-]	H_b/d_b [-]	K [-]	γ [-]	B [-]
	0.0025	1.2-1.8	0.35-1.0	0.5	5.0-20.0
	0.0035	0.8-1.1	0.15-0.35	0.3 -0.5	1.0-10.0
	0.0070	0.7-1.1	0.15-0.35	0.25-0.35	1.0-10.0
	0.0110	0.7-0.9	0.2 -0.25	0.35	1.0

Table 1: Variations of parameters K and γ for DALLY et. al. and B for BATTJES' models to minimize the differences between measured data and computed values.

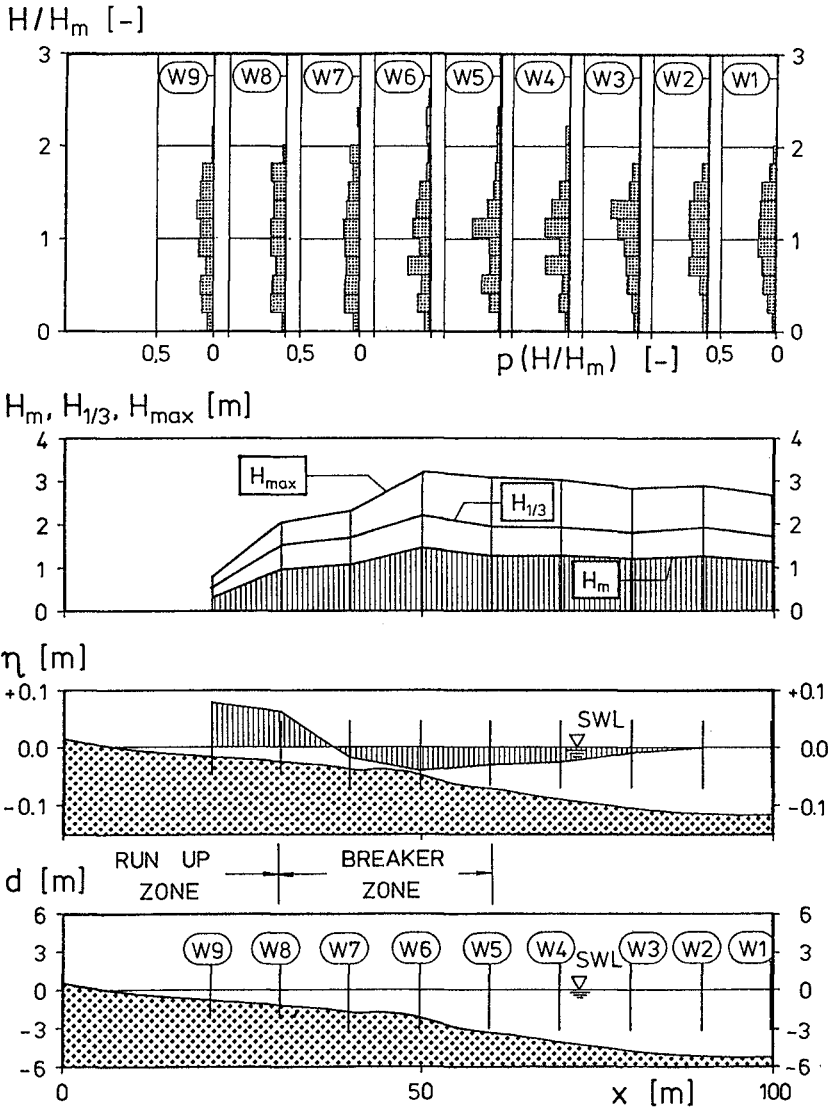

Fig. 3: The results of statistical analysis for a spectrum of $H_s = 1.5$ m and $T_p = 6.0$ s

Fig. 4: The results of spectral analysis for a wave spectrum of $H_s = 1.5$ m, $T_p = 6.0$ s, where n_0 and n_2 denotes the spectral moments

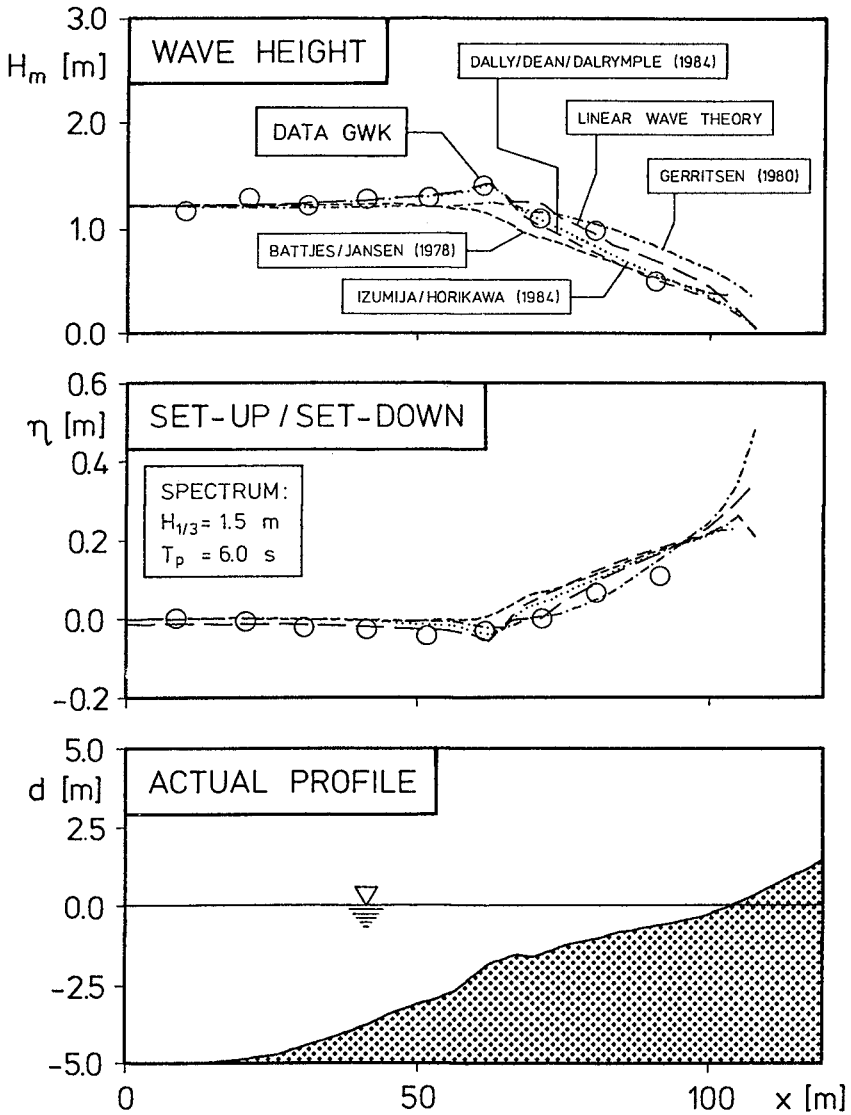

Fig. 5: Comparison of computed and measured values for a spectrum of $H_s = 1.5$ m, $T_p = 6.0$ s across the profile.

The above results, Fig 4, show, that (I) the energy density spectrum shows dissipation of wave energy in the breaker zone in direction of wave approach, $\Delta n_0 = 95 \%$, (II) the peak of the energy spectrum is reduced and, (III) the transformation of incident wave energy to lower and higher frequency contributions i.e. higher frequency oscillations and in the surf zone disintegration of waves and turbulence.

The statistical analysis of wave heights and comparison with selected wave height decay models show fairly good agreement between computed values and measured data, even for the more simple models predicting only regular waves (Fig.3 and Fig 5).

The comparison of measured and computed water level deviations shows slight underprediction of set-down and significant overprediction of set-up in the surf zone for the examples (Fig. 3 and Fig. 5).

3.3 Energy Dissipation of Waves in Field Investigations

Measurements of wave height have been recently started in a profile perpendicular to the shoreline at the west-coast of the island of Sylt (North Sea) near the village of Rantum with a typical nearshore bar- and trough topography. Using as initial values the measured data from a wave rider buoy offshore (10 m-depth) wave heights and set-up/set-down were computed by the models described in section 2.4 and compared with wave height measurements inside the surf zone.

Fig. 6 shows time series of measured and computed data for a storm event in february 1988 with offshore wave heights up to $H_s = 4.0$ m.

3.4 Application to a 2-Dimensional Nearshore Topography

A wave refraction model based on the wave ray method was adapted to the study site by implementation of a breaker criterium (WEGGEL(1972)), a wave height decay model (ANDERSON/FREDSØE (1983)) and a criterion of wave height stabilization (TUCKER et al. (1983)).

The topography of the investigation area was taken into account up to the MSL-10.0 m depth contour line. Fig. 7 shows as an example areas of wave height exceedance in the nearshore topography, the breakpoints (●) and points of restabilization (o) for incident wave parameters of $H = 6.0$ m , $T = 10.0$ s and the direction of wave approach perpendicular to the shore.

Fig. 6: Comparison of computed values and measured data for a storm event at the west coast of the Island of Sylt/North Sea

The contour lines of equal wave height indicates the effect of morphological elements as the bar (breaker zone) and the gap in the bar (wave energy intake into the trough region).

First comparisons of measured wave heights and computed wave heights show generally fairly good agreement but in some cases significant differences arise due to the inadequacy of the energy dissipation formulation. Therefore it is the task to combine one of the more sophisticated models mentioned in section 2. with the refraction model in order to obtain better agreement between computed and measured wave parameters.

4. Discussion

Measurements in the Big Wave Flume (GWK) and at the west coast of the Island of Sylt have been carried out with respect to energy dissipation due to breaking waves. The wave height decay of individual waves and of irregular wave trains were analysed and compared with empirical and analytical models which partly take the effects of wave height distribution into account to predict the wave height variation and wave set-up/set-down over a profile.

For individual waves good agreements were found for moderate energy dissipation conditions (spilling breakers). The energy dissipation of plunging breakers, however, is not satisfactory described.

The application to a nearshore site with rough and varying topography is still under investigation. The models tested with full scale experiment data were found to predict wave height decay quite well for the 1-dimensional case.

For the rough varying bar and trough profile at the west coast of Sylt significant differences were found due to the different treatments of regular waves, irregular waves and the breakpoint formulation.

The models will be tested in combination with a refraction model to obtain a suitable description of wave energy dissipation in a 2-dimensional topography.

5. Acknowledgments

The authors are indebted to the Deutsche Forschungsgemeinschaft (DFG) and the German Ministry of Research and Technology (BMFT) for their sponsorship of the Big Wave Flume experiments and the research-projekt " Optimization of Coastal Protection at the Island of Sylt ".

CHAPTER 21

TRUNCATION ORDER OF FOURIER WAVE THEORY

Rodney J. Sobey¹, M.ASCE

Specific consideration is given to the dependence of Fourier wave solutions on both truncation order and the number of free surface nodes. Solution dependence is quantified by a comprehensive set of numerical experiments over a typical range of wave height, water depth, truncation order and overspecification values. Integral error measures include the rms free surface boundary condition errors and a slope error that identifies non-physical positive slope segments in the wave profile between crest and trough. Summary error diagrams are presented as a guide to the adoption of suitable truncation orders and overspecification for Fourier solutions. The truncation order is the crucial parameter but there is measurable advantage is some small overspecification.

INTRODUCTION

Fourier wave theory has proved to be a robust steady wave theory for almost the complete range of wave heights, water depths and uniform currents experienced in practice. It is a hybrid analytical/numerical theory. The analytical aspects are relatively straightforward though not entirely without difficulties. The numerical part of the solution however is distinctly nontrivial. It involves the simultaneous solution of a large number of implicit nonlinear algebraic equations in a large number of unknowns. This is recognized as an extremely difficult problem in numerical analysis for which a successful solution algorithm depends critically on the analytical formulation of the problem and on the physical nature of the solution. For waves of small to moderate height in relatively deep water, successful solutions do not appear to be difficult to obtain. For higher waves in deep water and especially waves of moderate to large height in shallow water, changes in the physical nature of the solution significantly complicate the achievement of a successful solution. So much so in fact that it becomes appropriate to consider just what is a successful solution. The complexity of the numerical solution procedure has tended to distract attention from this rather more fundamental question, namely, whether an achievable numerical solution can be equated with a reasonable physical solution of a particular steady wave problem.

STEADY WAVE THEORY

Progressive waves of permanent form are steady in a frame of reference moving at the phase speed C . Accordingly, it is convenient to adopt a steady and moving x,z reference frame that is located at the mean water level (MWL) and moves at speed C with the wave crest, rather than an unsteady and fixed X,Z reference frame. The field solution is described by the stream function $\psi(x,z)$. Assuming that the flow is incompressible and irrotational, the field equation representing mass and momentum conservation is the Laplace equation

¹ Professor, Hydraulic and Coastal Group, Department of Civil Engineering, University of California at Berkeley, Berkeley, CA 94720

$$\frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial z^2} = 0 \quad (1)$$

where the velocity components (u,w) are $(\partial\Psi/\partial z, -\partial\Psi/\partial x)$.

This field equation is subject to the following boundary conditions:

(1) Bottom boundary condition, representing no flow through the horizontal bed, is

$$\Psi(x, -h) = 0 \quad \text{at } z = -h \quad (2)$$

(2) Kinematic free-surface boundary condition (KFSBC), representing no flow through the free surface, is

$$\Psi(x, \eta) = -Q \quad \text{at } z = \eta(x) \quad (3)$$

where $\eta(x)$ is the free surface and $-Q$ is the constant volume flow rate per unit width under the steady wave. Q is positive and this flow is in the negative x direction.

(3) Dynamic free surface boundary condition (DFSBC), representing constant atmospheric pressure on the free surface, is

$$\frac{1}{2} \left(\frac{\partial \Psi}{\partial x} \right)^2 + \frac{1}{2} \left(\frac{\partial \Psi}{\partial z} \right)^2 + g\eta = R \quad \text{at } z = \eta(x) \quad (4)$$

where g is the gravitational acceleration and R the Bernoulli constant.

(4) Wave is periodic.

$$\Psi(x + L, z) = \Psi(x, z) \quad (5)$$

where $L (= 2\pi/k)$ is the wave length and k is the wave number

Given parameters defining a steady wave solution are generally the wave height H , the water depth h , the wave period $T (= 2\pi/\omega)$ and either the coflowing Eulerian current C_E or the wave-averaged mass transport velocity or Stokes drift C_S . The wave height is defined as

$$H = \eta(x=0) - \eta(x=L/2) \quad (6)$$

and mass conservation requires an invariant MWL such that

$$\int_0^{L/2} \eta(x) dx = 0 \quad (7)$$

The speed C of the moving and steady reference frame is related to the fixed and unsteady reference frame by the dispersion relationship. Where C_E is known, the dispersion relationship is

$$C = \frac{L}{T} = \bar{u} + C_E \quad (8)$$

where \bar{u} is the mean fluid speed at any z wholly within the fluid. The Stokes drift is then defined as

$$C = \frac{L}{T} = \frac{Q}{h} + C_S \quad (9)$$

Where C_S is known, Equation 9 is the dispersion relationship and Equation 8 is the definition equation for C_E .

FOURIER WAVE THEORY

The solution for the stream function is represented by a truncated Fourier series

$$\Psi(x, z) = -\bar{u}z + \frac{g^2}{\omega^3} \sum_{j=1}^N B_j \frac{\sinh jk(h+z)}{\cosh jkh} \cos jkx \quad (10)$$

where the B_j are the dimensionless Fourier coefficients, of which there are N . This representation of the stream function automatically satisfies the field equation, the kinematic bottom boundary condition and the periodic lateral boundary conditions. The Fourier coefficients are chosen numerically to satisfy the free surface boundary conditions, the finite truncation order N being the only necessary assumption in the analytical formulation of Fourier wave theory.

The unknown variables in a Fourier wave solution are k, \bar{u}, C_E or C_S, Q, R , the η_m for $m=0(1)M$ and B_j for $j=1(1)N$, of which there are $M+N+6$ in total. The $\eta_m = \eta(x_m)$ are water surface nodes, where the $x_m = (m-1)\pi/kM$ are uniformly distributed in x from crest to trough.

The problem formulation provides $2M+6$ implicit algebraic equations in these $M+N+6$ unknowns, each equation being cast in the form

$$f_i(k, \bar{u}, C_E \text{ or } C_S, Q, R, \eta_m, B_j) = 0 \quad (11)$$

The equations define the wave height

$$f_1 = \eta_0 - \eta_M - H \quad (12)$$

the mean water level

$$f_2 = \frac{1}{2M} \left(\eta_0 + 2 \sum_{m=1}^{M-1} \eta_m + \eta_M \right) \quad (13)$$

the Eulerian current

$$f_3 = \frac{2\pi/k}{T} - \bar{u} - C_E \quad (14)$$

the Stokes drift

$$f_4 = \frac{2\pi/k}{T} - \frac{Q}{h} - C_S \quad (15)$$

the kinematic free surface boundary condition (KFSBC) at each of the $M+1$ free surface nodes

$$f_{5+2m} = \Psi(x_m, \eta_m) + Q \quad (16)$$

and the dynamic free surface boundary condition (DFSBC) also at each of the free surface nodes

$$f_{6+2m} = \frac{1}{2} \left[\frac{\partial \Psi(x_m, \eta_m)}{\partial x} \right]^2 + \frac{1}{2} \left[\frac{\partial \Psi(x_m, \eta_m)}{\partial z} \right]^2 + g \eta_m - R \quad (17)$$

Note in particular the use of the trapezoidal rule in Equation 13 for the MWL. This is an exact result for the continuous integral in Equation 7 where $\eta(x)$ is represented by a truncated Fourier series, as is implied by Equation 10.

The problem is uniquely defined for $M = N$ and overspecified for $M > N$. The solution of a set of $2N+6$ simultaneous implicit algebraic equations in $2N+6$ unknowns is a familiar problem in numerical analysis for which successful algorithms are generally variations on the Newton-Raphson method. A set of $2N+6$ simultaneous implicit algebraic equations in $M+N+6$ unknowns, where $M > N$, is an equally familiar problem in numerical analysis in the context of nonlinear optimization. A solution is established by seeking a minimum value for an objective function of the $M+N+6$ unknowns. A familiar algorithm is the least squares method where the objective function is the sum of squares of the left hand sides of the $2M+6$ equations.

$$O(k, \bar{u}, C_E \text{ or } C_S, Q, R, \eta_m, B_j) = f_1^2 + f_2^2 + \dots + f_{2M+6}^2 \quad (18)$$

Such an algorithm is equally successful for $M = N$ where the objective function would be expected to be zero. In practice, this involves little sacrifice in computational efficiency and none in solution precision and is accordingly a convenient choice of algorithm for the present purposes.

The choice of numerical solution algorithm should not influence the solution and the present computations have exclusively adopted the IMSL subroutine ZXSSQ, which is a finite-difference Levenberg-Marquardt algorithm with strict descent in double precision. This algorithm is mature, routinely successful and commonly available. Given that a solution exists, there are two potential difficulties with any optimization algorithm. The first is the difference in physical dimensions and relative magnitudes of the dependent variables. This has been minimized by redefining the variables and the implicit algebraic equations in dimensionless form, here in terms of ω and g . Subse-

quently, all constants and variables are non-dimensional, simply achieved by setting $\omega = g = \rho = 1$. A second difficulty is the potential existence of multiple solutions, especially the odd harmonics which are legitimate mathematical solutions of the gravity wave problem as formulated. This problem can be avoided, for example, by the choice of an initial estimate of the complete solution from Airy wave theory at a fraction of the given wave height. The wave height is then progressively increased towards the given wave height, with an initial estimate at each subsequent step being provided by a Taylor series expansion in H about the converged solution at the previous height step. A fraction sequence of 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1.0 has been employed, with two steps normally sufficient in very deep water, four in transitional water and all seven in extremely shallow water.

Whether a solution exists at all is a further potential difficulty and there are two aspects here that require attention. The first is the truncation order N of the Fourier series. Steep crest and flat trough profiles typical of shallow water waves require many more Fourier terms than the more closely sinusoidal wave profiles in deep water. The theoretical slope discontinuity at the crest of limit waves would require an infinite truncation order and can not be accommodated by Fourier wave theory; in practice however, adequate solutions can be achieved very close to this limit. The second aspect is whether or not a solution does indeed exist and here the problem formulation is remarkably prophetic and robust. Convergence is just not achieved for the present formulation, despite the mathematical possibility of a minimum of the objective function, at combinations of dependent variables that are not physically possible. This is an especially encouraging aspect of the problem formulation and the numerical solution, considering the extreme multi-dimensionality of the problem and the considerable potential for spurious solutions.

Previous formulations of Fourier wave theory (Dean 1965 & 1974, Dalrymple 1974, Chaplin 1980, Rienecker & Fenton 1981) have been reviewed in detail elsewhere (Sobey 1988) and compared with the present generalized formulation. Differences are more apparent than real. The Dean, Dalrymple and Chaplin algorithms lack some flexibility in excluding Stokes second definition of phase speed. The present algorithm is a modification (normalized by known wave frequency rather than unknown wave number) and generalization (M can be greater than N) of the Fenton (1983) version of the Rienecker and Fenton formulation. All algorithms were shown to provide essentially identical results with Stokes first definition of phase speed for wave height up to at least 90% of the breaking wave height. The slope discontinuity for limit waves requires an infinite Fourier series which is beyond the capabilities of a truncated Fourier series. Substantially increasing the truncation order (Chaplin uses $N=51$ at 90% of breaking wave height) improves fidelity for near-limit waves but finite machine precision rapidly limits the utility of this approach. Numerical solutions for nominally limit waves at finite truncation orders by Dean (1974) have been shown to be spurious solutions by Chaplin (1980), as they do not capture the dual-valued nature of integral properties of near-limit waves.

Given the essentially complete agreement among Fourier wave theory formulations for small to moderately extreme wave heights, the present generalized formulation can be utilized in an analysis of solution characteristics in the reasonable expectation that the results will be applicable also to alternative formulations. Limit waves can not be accommodated by any Fourier formulation and will not be included in the analysis, which will focus on small (Dean case A at 25% of empirical breaking wave height) and moderately extreme (Dean case C at 75% of empirical breaking wave height) waves.

ERROR MEASURES

Fourier wave theory has but two assumptions, the truncation order N and the number of water surface steps $M+1$. Given that M must be greater than or equal to N for closure, it is convenient to define the overspecification $MN = M - N$. Both N and MN influence the fidelity of the solution and, being the only assumptions of the theory, there is considerable value in documenting the numerical solution dependence on both parameters. The influence of truncation order is implicit in most published solutions,

with adopted N values increasing from small to high waves and especially from deep to shallow water. The influence of MN is rather less obvious. Dean and Dalrymple do not record M , beyond a statement to the effect that M is large. Chaplin apparently uses $M=200$ but Rienecker and Fenton use $M=N$, i.e. $MN=0$. In principle and frequently in practice, numerical solutions are achievable for all $N \geq 1$ and all $MN > 0$. Spurious solutions may result from inappropriate choices of both N and MN . The truncation order is broadly analogous to order of an analytical waves theory such as Stokes or cnoidal; it should not be too small but what is large enough? Similarly, what is an appropriate value for MN ? It is implicit in the Dean, Dalrymple and Chaplin formulations that a "large" value of MN is essential for solution fidelity. How large is "large"? Some guidance in answering these questions can be provided from the analysis of numerical solutions over a range of N and MN values.

Figure 1 DFSBC Error Traces for Case 3C

Error measures must be defined to assist in this analysis. Two appropriate objective criteria follow naturally from the problem formulation, where only the free surface boundary conditions are not satisfied exactly. The residual error in the KFSBC is

$$K(x) = \psi(x, n) + Q \quad (19)$$

Similarly, the residual error in the DFSBC is

$$D(x) = \frac{1}{2} \left(\frac{\partial \psi}{\partial x} \right)^2 + \frac{1}{2} \left(\frac{\partial \psi}{\partial z} \right)^2 + g\eta - R \tag{20}$$

These error traces oscillate about zero in a manner typical of truncated Fourier series. The Fourier solution satisfies these boundary conditions at discrete, uniformly spaced surface nodes, not along the entire free surface. This is illustrated in Figure 1 for Dean Case 3C ($\omega^2 h/g = 2\pi/100$; $\omega^2 H/g = 0.03657$, $C_n = 0$) for $D(x)$ over a range of N and MN , each profile being based on 100 points between crest and trough. The truncation order influences these traces directly, there being exactly N oscillatory cycles per wavelength. For $MN = 0$, the zero crossings of the error traces identify the locations of the free surface nodes. Overspecification MN influences the phasing and amplitude of these traces, generally decreasing the amplitude of the oscillation, except where the truncation order is ridiculously small ($N = 1$). The principal advantage of overspecification would appear to be the change in the phasing of the error traces; the free surface nodes are moved from the natural zero-crossings of the N -term finite Fourier series and the amplitude of the trace oscillations is damped significantly in consequence. The markers on Figure 1 are the published Dean (1974) solution (where $N=17$, $MN=36n-17$, n being an unrecorded integer). These errors are given to only one significant figure and are indicated by error bands, but are nonetheless entirely consistent with the present results. The phase reversal is apparently a consequence of the different numerical optimization algorithms and is not believed to be significant. In all cases except the trivial $N = 1$, the trace amplitude is a maximum at the crest and decays rapidly in magnitude towards the trough.

Figure 2 KFSBC Error Traces for Case 3C

The KFSBC error trace $K(x)$ behaves similarly and is shown in Figure 2 for the same Dean case 3C solutions as in Figure 1. Dean (1965, 1974) defines the KFSBC errors as $dn/dx - u/w$, which is not directly comparable with Equation 19. It is emphasized in the Dean (1965, 1974) formulation of Fourier wave theory that the KFSBC is exactly satisfied but this is a misleading statement (Sobey 1988). Dean has adopted a multi-step solution algorithm that decouples the KFSBC from the balance of the problem formulation and assumes that k , R , Q and the B_j coefficients are given parameters, equated to the most recent estimates from earlier steps in the iterative algorithm. This is a significantly weaker statement that cannot be categorized as exact. KFSBC errors as defined by Equation 19 will remain.

Single number measures of these boundary condition error traces are conveniently provided by the root-mean-square values (Dean 1974), as

$$\epsilon_{KFSBC} = \frac{1}{J+1} \sum_{j=0}^J K^2(x_j) \quad (21)$$

and

$$\epsilon_{DFSBC} = \frac{1}{J+1} \sum_{j=0}^J D^2(x_j) \quad (22)$$

where the x_j are evenly spaced between crest and trough and J should significantly exceed M ; $J=100$ was adopted throughout. Note however that these error measures will be artificially small if J is chosen to correspond with the surface nodes, e.g. $J = M = N$.

Figure 3 Slope Traces for Case 3C

The influence of the truncation order is implicit in the free surface boundary condition errors which provide a measure of a satisfactory numerical solution but not an especially direct measure of just what is a satisfactory physical solution. The direct influence of truncation order is rather more apparent from specific consideration of the truncated Fourier series approximation. Fourier series approximations to near sinusoidal profiles are quite trivial but the sharpening of the crest profile and flattening of the trough profile, that is experienced for higher waves in deep water and almost all waves in shallower water, requires a rapidly increasing truncation order. Insufficient Fourier terms will result in the Gibbs phenomenon and non-physical profile oscillations. In principle, a physical wave profile should be monotonically decreasing from crest to trough; the profile slope $S(x) = d\eta/dx$ should never be positive. Figure 3 shows water surface slope traces for the same Dean case 3C solutions as in Figures 1 and 2, except that the Dean tabulated solution does not provide this information. The slope traces assist in identifying profile oscillations in the long flat trough profiles. Where the truncation order is insufficient, the slope traces oscillate above and below the zero level. These slope traces are especially sensitive to truncation order and overspecification and an additional error measure is provided by the positive area under the slope traces

$$\epsilon_{Slope} = \int_0^{L/2} \left[\frac{d\eta}{dx} \right]_{+} dx \quad (23)$$

the + subscript indicating the inclusion of only those segments of the profile where $d\eta/dx \geq 0$. Physically satisfactory solutions should have a zero slope error.

Collectively, the KFSBC, DFSBC and water surface slope errors provide a reasonably comprehensive measure of the analytical veracity of a Fourier wave solution. In addition, the slope errors provide an excellent indication of the physical suitability of a computed solution.

NUMERICAL EXPERIMENTS

Any Fourier wave solution is in principle dependent on three physical parameters wave height $\omega^2 H/g$, water depth $\omega^2 h/g$, and current $\omega C_v/g$ or $\omega C_s/g$ and on two numerical parameters truncation order N and overspecification MN . The three integral error measures defined above are then dependent on these five parameters. The details would be available from a comprehensive range of numerical. Each of these solutions is computationally intensive and exhaustively covering this five parameter space would be a massive computational task. A representative yet still reasonably comprehensive set of solutions were undertaken, based essentially on Dean case C at 75% of an empirical depth-dependent breaking wave height and $\omega C_v/g = 0$. Water depth $\omega^2 h/g$ values included Dean cases 3 ($\omega^2 h/g = 2\pi/100$), 4 ($2\pi/50$), 5 ($2\pi/20$), 6 ($2\pi/10$), 7 ($2\pi/5$), 8 (π) and 10 (4π). Case A solutions at 25% of an empirical depth-dependent breaking wave height were also computed for depth cases 3, 6 and 10. For each of these ten wave height - water depth combinations, solutions were computed for truncation orders $N = 1(5)21$ and overspecification $MN = 0(10)30$; MN extended from 0(10)50 for cases 3C, 4C and 7C. A total of 230 separate Fourier wave solutions were completed, which collectively provide an overall perspective on the N and MN dependence throughout the practical range of wave height and water depth values.

For each Dean case there are 20 or 30 separate solutions and results are conveniently presented as three dimensional bar charts for each dimensionless integral error measure and each Dean case. Even so there are 30 such plots and only selected examples can be included. The previous discussion has highlighted Dean case 3C and Figures 4, 5 and 6 show the corresponding integral error plots for the DFSBC, the KFSBC and the slope. As an aide to interpretation, these dimensionless plots are all to the same scale. They are truncated at 10^{-6} , a convenient number that does not absolutely identify a successful solution but is strongly suggestive of one.

Figure 4 for the DFSBC shows a dependence on both truncation order and overspecification as anticipated by Figure 1. For $MN = 0$, there is a steady decrease in the rms error with increasing truncation order. Increasing overspecification has an immediate influence in significantly decreasing the rms error; further increases in MN have limited influence. The nature of this presentation however is rather deceptive of the computational effort involved. Computational effort is directly related to $(2M + 6)^2$, where $M = N + MN$. Designating computational effort as E^2 , truncation order and overspecification are related as

$$N + MN = E - 6 \quad (24)$$

which can be represented on Figure 4 as straight line lines intersecting both the N and MN axes at the same numerical values. The dashed lines on the base plane of Figure 4 indicate lines of equal computational effort, which put the combined influence of both N and MN in better perspective. As perhaps expected, the rms error is rather more directly related to computational effort (i.e. $N + MN$) than to either N or MN separately. Increasing MN alone may lead to a spurious result as the rms error very rapidly reaches a plateau level. Increasing N alone however leads to a consistent decrease in the rms error. It is apparent that truncation order is the crucial parameter. Overspecification can provide some measurable advantages but arguably no more (and potentially much less) than an equivalent increase in the truncation order to achieve the same computational effort.

Figure 4 Rms DFSBC Error for Case 3C

Figure 5 Rms KFSBC Error for Case 3C

Figure 6 Slope Error for Case 3C

Figure 5 for the KFSBC shows a very similar trend as does Figure 6 for the water surface slope. The base levels at $N = 1$ are clearly spurious solutions; they predict a near-sinusoidal wave as is apparent from the equivalent slope traces in Figure 3. The overall picture presented by each of the three integral error plot is very similar, but there is one essential difference however. The rms errors in the free surface boundary conditions must approach zero asymptotically, whereas the slope error may suddenly jump to zero at finite values of the rms boundary errors. At the 10^{-6} level, oscillations in the trough profile at barely perceptibly and certainly define a pragmatic solution. Higher cutoff levels may in fact be acceptable. It would appear nonetheless that the slope summary plot provides a useful measure of an acceptable solution, both mathematically and physically.

Space limitations preclude presentation of all the summary plots. Sufficient detail is provided by one of the rms error plot (say DFSBC) together with the slope plot. Figure 7 shows these error plots for Dean case 3A ($\omega^2 h/g = 2\pi/100$; $\omega^2 H/g = 0.01224$, $C_p = 0$) at 25% of the empirical breaking wave height. The significantly lower wave height is much less demanding of the Fourier wave theory and the 10^{-6} base levels are rapidly achieved for both the rms DFSBC error and the slope error.

Figure 8 through 14 shows the summary plots for Dean cases 4C, 5C, 6A, 6C, 7C, 8C and 10C respectively. These plots clearly demonstrate the relative ease with which acceptable solutions are achieved in deeper water. Case 4C (Figure 8) follows a very similar trend to Case 3C but profile steepness is not quite as extreme in the slightly deeper water and the 10^{-6} base level is reached with somewhat less computational effort. Case 5C (Figure 9), 6C (Figure 11) and 7C (Figure 12) continue this trend, slope errors becoming rapidly less problematic. In fact, slope errors appear not to be a serious problem in deeper water. A comparison of Case 6A (Figure 10) and Case 6C (Figure 11) once again demonstrates the relative ease with which Fourier solutions are achieved at lower wave heights.

The Case 8C (Figure 13) summary plot continues these trends in very deep water, except that the DFSBC (and also the KFSBC which is not included) errors reveal an additional problem at $N = 21$, $MN = 0$. The Case 10C solution (Figure 14) follows the same trend but not the Case 10A solution (not included). Perusal of the solution details reveals that this apparent problem is a consequence of finite compiler and machine precision. The Fourier coefficients become very small very rapidly in deep water and the higher coefficients are typically fifteen orders of magnitude smaller than the leading B_1 coefficient. This confronts the capabilities of double precision arithmetic (REAL*8 variables in Fortran), although this is both compiler and machine dependent. In such a

Figure 7 Error Summary for Case 3A

Figure 8 Error Summary for Case 4C

Figure 9 Error Summary for Case 5C

Figure 10 Error Summary for Case 6A

Figure 11 Error Summary for Case 6C

Figure 12 Error Summary for Case 7C

Figure 13 Error Summary for Case 8C

Figure 14 Error Summary for Case 10C

case it is possible to adopt too high a truncation order, very much the reverse of the more serious problems in shallower water. A truncation order of 21 is unnecessary in deep water.

In the application of analytical wave theories such as Stokes and cnoidal, the choice of an appropriate order is a matter of engineering judgement, and depends upon the nature of the physical problem, the required precision of the computation and sometimes on overriding regulatory requirements. The choice of truncation order and overspecification for Fourier wave theory is similarly a matter of engineering judgement and it is not appropriate to nominate specific values. The consequences of a particular choice however can be evaluated from the range of summary plots presented that have been presented.

CONCLUSIONS

Each Fourier wave solution is nominally dependent of three physical parameters, wave height $\omega^2 H/g$, water depth $\omega^2 h/g$, and current $\omega C_v/g$ or $\omega C_s/g$ and on two numerical parameters truncation order N and overspecification MN . Specific attention has been given to the solution dependence on N and MN and to the distinction between a successful numerical solution and a successful physical solution.

Some 230 separate Fourier wave solutions have been completed over a wide parameter range representative of field conditions. Trends are summarized in terms of three integral error measures, the rms DFSBC and rms KFSBC errors, which are measures of a successful numerical solution, and a slope error, which is a measure of a successful physical solution. A dimensionless cutoff level of 10^{-6} has been adopted to identify a successful solution. Precision is shown to be closely related to computational effort ($N + MN$) but the truncation order N is the dominant parameter. There is some minor advantage in a little over specification but significant overspecification does not enhance precision.

A range of summary error plots should assist in the rational assignment of truncation order and possible overspecification for Fourier wave solutions.

CHAPTER 22

DIRECTIONAL SEA STATE NEAR THE ISLAND OF SYLT

by

Daniel Schade ¹⁾, Karl-Friedrich Daemrich ²⁾

Abstract

In the scope of a joint research program dealing with erosion problems of the island of Sylt in the North Sea, wave measurements with two pitch-and-roll buoys are carried out in order to obtain more detailed information on the sea state with regard to wave dependent morphological processes.

The instrumentation is described. Results from the directional analysis of closely spaced buoys are compared, showing good agreement in significant parameters and in distributions in the frequency range. Differences between wave and wind directions are discussed. A method of separating double peak spectra by fitting theoretical shallow water spectra to the measured energy density distributions is presented.

1. Introduction and scope of investigations

The island of Sylt is one of the North Frisian Islands, located in the southeastern part of the North Sea (fig.1). The main dimensions are about 40 km in north-south direction and 1 to 4 km in east-west direction, except the central part. The main wave directions are from the west, striking the islands broadside.

D-3000 Hannover 1, F.R.G.

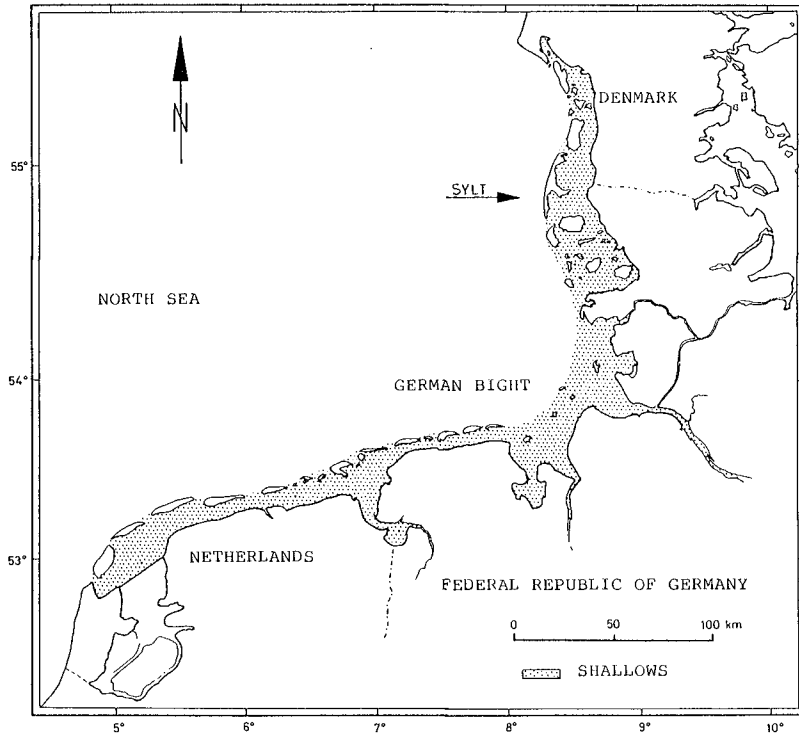

Fig.1:
Location of the island of Sylt in the North Sea

Due to the exposed site of the island the erosion has been a serious problem for centuries. This could not be stopped even with intensified shore protection works, e.g. the construction of groynes and revetments started in 1865 and by beach nourishments since 1972. During the last 35 years the island lost an area of about 2.50 km^2 equivalent to a quantity of some $50 \cdot 10^6 \text{ m}^3$ material.

In 1985 a joint research program was created to deal with the problems of the island and work towards an optimization of coast protection measures. Scientists from various German universities and the Amt für Land- und Wasserwirtschaft Husum (local technical authority) are participating in this project.

One part of this research program realized by the Franzius-Institut is to carry out measurements with two pitch-and-roll buoys in order to obtain directional wave spectra.

The main task of these measurements is to provide more detailed information on the sea state as a basis and reference for the wave related investigations within this

research program. Especially the directional information, essentially important for the judgement of longshore sediment transport processes, was not available up to now and had to be estimated on the basis of wind information.

In this contribution the following topics are treated:

- description of the instrumentation
- comparison of results from closely spaced Wavec buoys
- comparison of wind versus wave direction
- treatment of double peak spectra.

2. Instrumentation

For the investigations it was decided to procure the Datawell wave direction measuring system (fig.2). The buoy has a total weight of 700 kg, its diameter is 2.50 m. The mooring system consists of a mooring cross, 30 m rubbercord with a safety line (maximum load 8 t) and a 2 t heavy chain as an anchor weight.

The buoy measures vertical acceleration (heave) and pitch and roll angles against buoy defined x- and y- directions.

Fig.2:
Wavec pitch-and-roll buoy

The land station on Sylt consists of a Direc receiving station, a HP85 deskcomputer and a HP winchester disc for each buoy. The data are decoded and analysed by the Direc and then plotted and stored by the HP85 and the winchester disc. In the standard mode every 4 hours a 30 min series of data are processed and stored. The main computer in Hannover, 400 km southwards, is connected by telephone data line for

- transmission of the measured data
- function control
- change of the measuring mode.

For the processing of the measured time series, the Datawell standard package is used to calculate

- energy density spectrum
- mean direction for each frequency
- beam width of directional distribution

according to the methods established by LONGUET-HIGGINS et al. (1963).

3. Comparison of results from closely spaced buoys

It was decided to have one buoy at a permanent position as a basis and reference for the long term wave statistics. The second buoy is assigned for measurements in areas of special investigations along the island, but also for investigations of variations of the sea state, including shoaling and refraction. In a first measurement series, the buoys were located for a period of about 7 month in a distance of less than 1000 m (water depth of about 13 m below MSL) for the assessment of the reliability of the measuring system and the homogeneity of the wave field.

Significant parameters

$$\begin{aligned}
 H_S - \text{significant wave height} &= H_{m_0} = 4 \cdot \sqrt{m_0} \\
 & m_0 = \int_0^{\infty} S(f) \cdot df \\
 T_Z - \text{significant wave period} &= T_{0,2} = \sqrt{\frac{m_0}{m_2}} \\
 & m_2 = \int_0^{\infty} S(f) \cdot f^2 \cdot df \\
 \bar{\theta} - \text{overall mean direction} &= \frac{1}{m_0} \cdot \int_0^{\infty} S(f) \cdot \theta_m(f) \cdot df
 \end{aligned}$$

were calculated and the results for October 1987 compared in fig.3 as scatter diagrams.

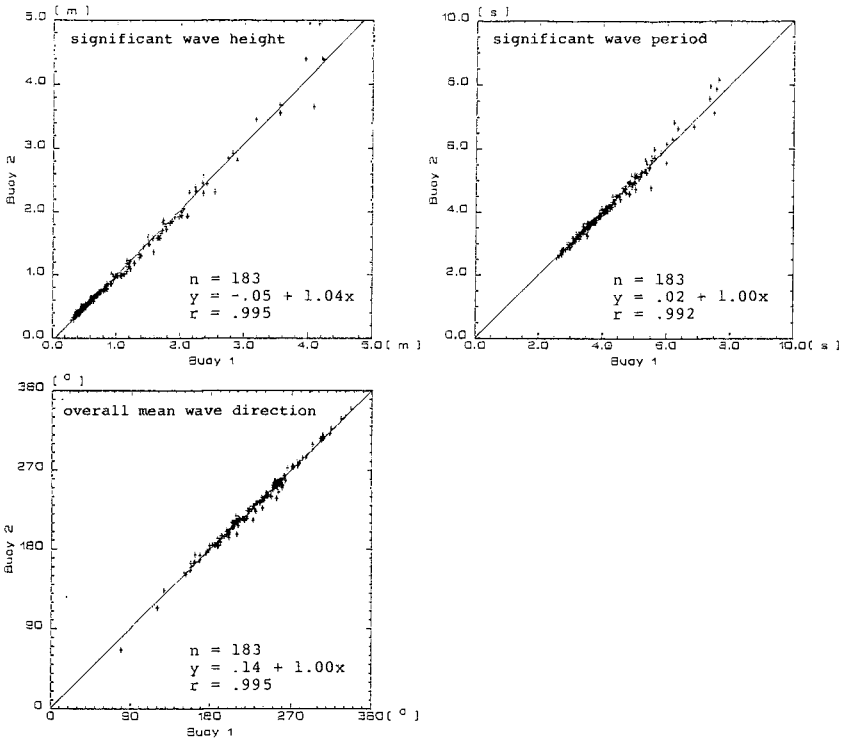

Fig.3:

Comparison of two closely spaced buoys, October 1987
linear regression

-significant wave height H_s [m]
-significant wave period T_z [s]
-overall mean wave direction $\bar{\theta}$ [°]

From the figures a good agreement can be seen. The correlation coefficient for all significant parameters is near to one.

In addition, the distribution in the whole frequency range was compared. Two examples are plotted, one with nearly identical significant parameters (fig.4) and one with some differences in the parameters (fig.5). In both cases the deviations are not too serious.

These results are in accordance with data presented by other authors (e.g. v.d.VLUGT, 1984).

4. Comparison of wind versus wave direction

One main part of this research program is to get better directional information and to check this against the wind direction, which was the up to now deepwater reference for the calculation of sediment transport rates.

Fig.5:

Comparison of directional spectra of two closely spaced buoys (16.10.1987 15.30)

Fig.4:

Comparison of directional spectra of two closely spaced buoys (16.10.1987, 19.00)

The wave and wind direction, together with the wave height and the wind speeds are compiled in monthly plots. In fig.6 the data for October 1987 are shown.

Fig.6:
Compilation of wave and wind parameters, October 1987

It is the general tendency, that fluctuations in wind direction are accompanied by minor fluctuations in wave direction. For easterly wind directions, i.e. wind from the land, no significant relationship can be expected, due to the still existing swell and wave heights below 0.5 m.

To investigate typical deviations, the wave directions were plotted directly against the wind directions for the period November 1987 to March 1988 (fig.7 a-c). The plot was restricted to events with westerly wave directions

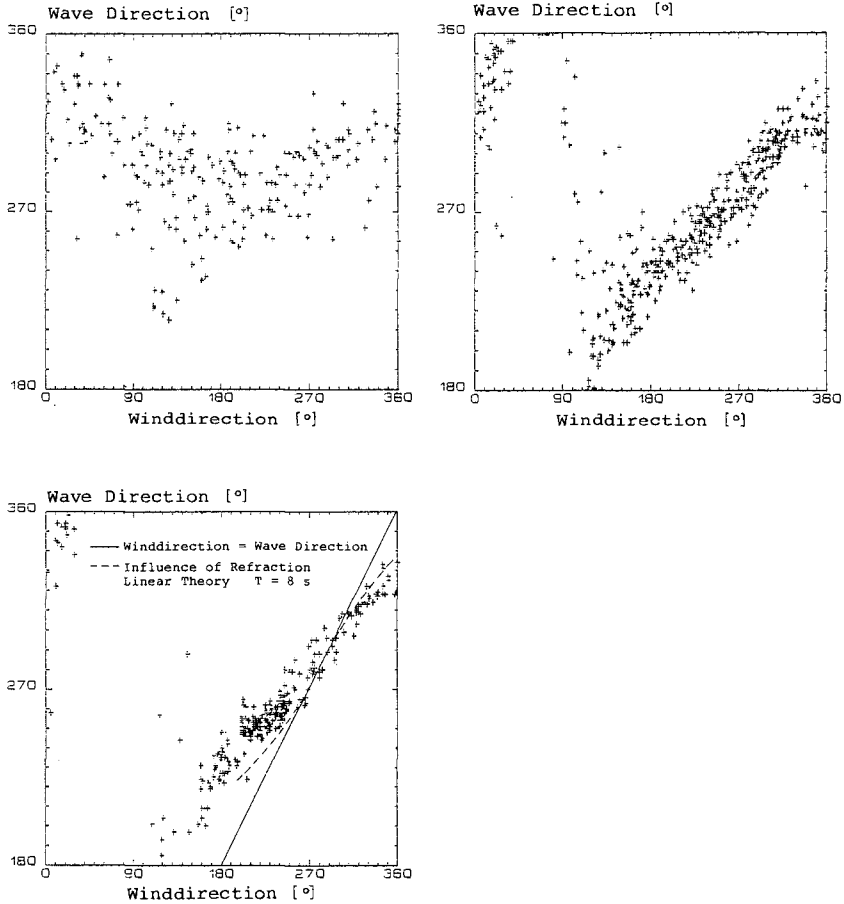

Fig.7:
Comparison of wind and wave direction
November 1987 - March 1988

a)	$u < 5$ m/s	n = 281
b)	$5 \text{ m/s} < u < 10$ m/s	n = 430
c)	$10 \text{ m/s} < u$	n = 288

between 180° to 360° . Besides that, a distinction was made between different groups of wind speeds (wind speeds and pertinent wind directions are 4 h averages of data preceding the wave measurements). Fig 7a shows a wide scatter, among others due to a great variety of wind direction at low wind speeds. In fig. 7b (wind speeds between 5 m/s and 10 m/s) a general tendency already appears in outlines, but still some remarkable scatter is left, due to influences from former events. In fig 7c the comparison is shown for wind speeds of more than 10 m/s. A distinct relation of the wave direction to the wind direction is now obvious.

Refraction influences were estimated with a regular wave model on the basis of linear wave theory, assuming parallel depth contours (strand orthogonal: 273° south part of the island, 290° north part of the island). According to the measurements, for wind speeds around 10 m/s a characteristic wave period of $T = 8$ s was used as input parameter. The result is plotted in fig. 7c for comparison (dotted line). Although the tendency of the results corresponds with the general trend of the deviation, this is not sufficient for application in design methods. A better agreement is expected from more sophisticated refraction models and considering results from measurements in deeper water with the second buoy.

5. Treatment of double peak spectra

It occurs, due to changing wind conditions, that a swell is superposed by a new generated wind sea. In the frequency domain, this may result in double peak spectra. The calculation of overall significant sea state parameters seems not to be sufficient in these cases (example see fig.8).

One way to identify these spectra and to separate for further working with significant wave parameters is to fit theoretical spectra, e.g. of the JONSWAP type, to the measured energy density distributions.

Fig.8:
Double peak spectrum 08.01.1987 00.30

As the JONSWAP shape is valid for deep water conditions, whereas the location of measurement is in a water depth of about 13 m below MSL, shallow water influences should be considered. To estimate the shape of the shallow water spectrum, the self similarity criteria as published by BOUWS et al. (1985), meanwhile well known as TMA shallow water spectrum (fig.9), were utilized.

Fig.9:
KITAIGORODSKII et al.'s ϕ as a function of ω_h
(after BOUWS et al. 1985)

By this method, it is possible to calculate a shallow water spectrum from a deepwater JONSWAP spectrum, using a transformation factor, which is a function of water depth and frequency. Using the TMA spectrum for the pertinent water depth a relatively good approximation to the measured spectrum was achieved (fig.10) by varying the PHILLIPS constant α and the peak enhancement factor γ . There is still some scatter, but the difference in significant wave heights is less than 5% in this example (4.5 m measured to 4.6 m calculated).

Fig.10:
Measured spectrum 10.2.1988 19.30 and pertinent TMA spectrum

For the separation and parameterization of a double peak spectrum, first the spectrum part with the lowest peak frequency is fitted by means of a TMA spectrum. The remaining part of the spectrum is then fitted by using the peak frequency of the second peak and the pertinent energy density reduced by the energy of the first spectrum at this frequency (example see fig.11).

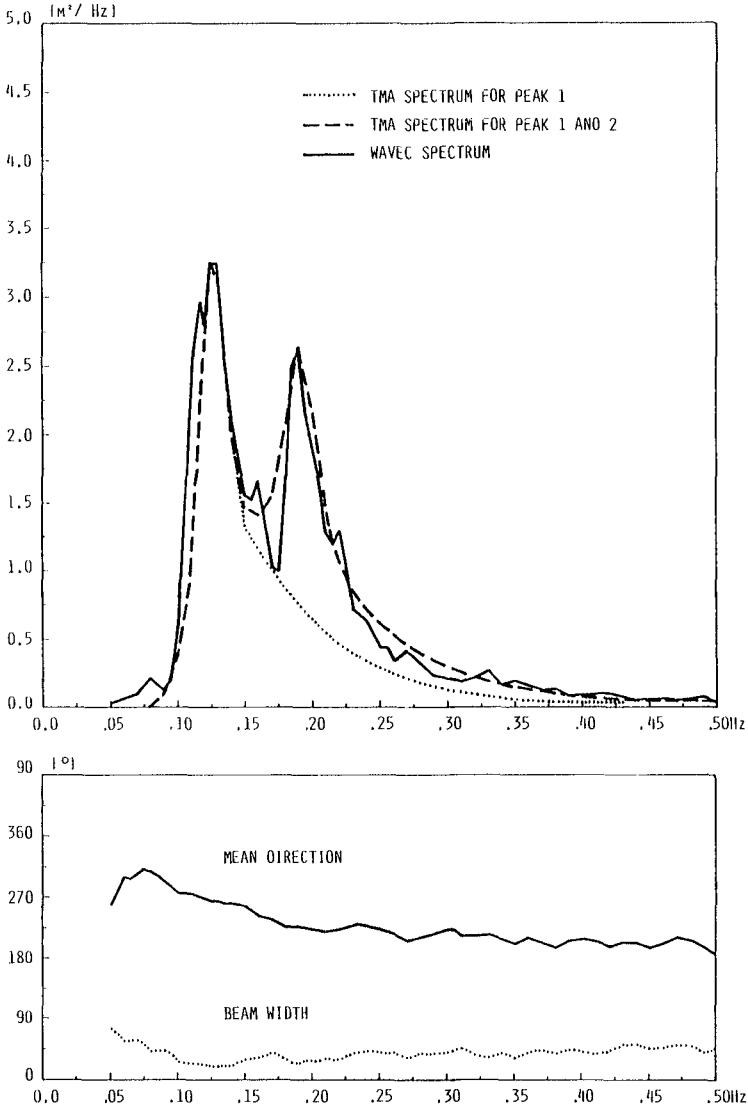

Fig.11:

Double peak spectrum 7.10.1987 16.30 and fitted TMA spectra

Using this parameterization approximate average wave directions could be calculated for each wave field. The wave parameters of the resulting TMA spectrum compared with the measured spectrum are as follows:

	H_s	T_z	T_p	$\bar{\theta}$
	m	s	s	°
measured spectrum	1.98	5.00	8.00	243
TMA 1	1.53		8.00	248
TMA 2	1.19		5.26	223

Fitting double peak spectra by this method has to be seen as a first attempt. In the scope of the project it is used to determine more reliable wave parameters for the estimation of longshore transport rates, e.g. by the CERC formula.

Assuming that both wave fields can be treated independently, two transport rates can be calculated and compared with the rate calculated from the overall parameters of the original spectrum. On a yearly basis $5.2 \cdot 10^6 \text{ m}^3$ are estimated from the first part of the spectrum (lower frequencies) and $2.4 \cdot 10^6 \text{ m}^3$ from the second part. The calculation with the overall parameters results in $9.8 \cdot 10^6 \text{ m}^3$. This is equivalent to a difference of about 25%.

CHAPTER 23

REDUCTION OF WAVE OVERTOPPING RATE BY THE USE OF ARTIFICIAL REEFS

by

Toru Sawaragi*, Ichiro Deguchi** and San-Kil Park***

ABSTRACT

A wave overtopping rate from a sea dike of various toe depths is formulated based on a weir model in an unidirectional flow. To evaluate the wave overtopping rate from a seadike on an artificial reef by the weir model, a numerical procedure for predicting wave transformations including the effect of forced wave breaking on the reef is constructed. After confirming the applicability of the model through experiments with regular and irregular waves, the effect of artificial reef on wave overtopping is discussed. So-called individual wave analysis method is shown to be applicable to the wave overtopping caused by irregular waves.

INTRODUCTION

To cope with the wave overtopping from existing seawalls and seadikes, various kinds of wave energy dissipating structures such as an offshore detached breakwater, armor blocks and so on have been used. The highest priority has been given to the wave energy dissipating function of these structures and utilization and the view of the coast have been left out of considerations.

In Japan, recently, an artificial reef has been widely constructed as a multi-purposed coastal structure to control coastal erosion, to reduce wave overtopping and to utilize coastal zone to the best advantage. The artificial reef usually consists of a submerged breakwater with broad crown width and an artificially nourished beach behind it.

*Professor and **Associate Professor, Dept. of Civil Engineering, Osaka University, Osaka, Japan

***Assistant Professor, Dept. of Civil Engineering, Pusan University, Pusan, Korea

The main function of the artificial reef is to make incident waves break forcibly and reduce wave energy in the nearshore zone.

The primary objective of this study is to investigate the effects of artificial reef on the reduction of wave overtopping rate from the vertical seadikes when the artificial reef is constructed in front of it.

The wave overtopping rate from the sea walls and seadikes on an uniformly sloping beach has been studied under various conditions. Most results of these studies are analyzed by using wave conditions in deep water and crest elevations from the still water (e.g. Goda(1985) and CERC(1984)). Therefore, the effects of artificial reef on wave overtopping can not be discussed based on these results because the incident waves in front of the seadikes are greatly altered by the reef.

In this study, the authors apply the weir model, in which wave heights in front of the seadike and the crest elevation of the seadikes from the mean water level are directly taken into account, to investigate the effect of the reef on wave overtopping. To utilize the model, it is necessary to evaluate wave conditions in front of the seadike. The authors also construct a numerical model for a prediction of wave transformation on the reef.

After confirming the applicability of the proposed model through experiments with regular and irregular waves, the effects of the artificial reef on the reduction of wave overtopping are discussed. A block diagram of this study is shown in Fig. 1.

Fig.1 A block diagram of the study

APPLICABILITY OF WEIR MODEL IN THE BREAKER ZONE AND DETERMINATION OF EXPERIMENTAL CONSTANTS OF THE MODEL

The weir model was originally proposed by Kikkawa et al. (1967) to estimate wave overtopping rate from the seadike in the region where the water depth at the foot of seadike is deep enough for the incident waves to form clapotis without breaking. They gave the following expressions for the wave overtopping rate on the basis of weir discharge in the uni-directional flow:

$$Q = \frac{4\sqrt{2g}}{3} m K^{3/2} H_i^{3/2} \int_{t_1/T}^{t_2/T} \left[F(t/T) - \frac{H_c}{KH_i} \right]^{3/2} d(t/T) \quad (1)$$

where Q is the wave overtopping rate per unit time and unit width of the seadike, H_i is the incident wave height in front of the seadike, H_c is the crest height from the mean water level, η_{max} is the maximum elevation of the surface in front of the seadike, t_1 and t_2 are the times when the surface elevation becomes H_c and $F(t/T)$ is the non-dimensional time variation of the surface elevation, $\eta(t)$, defined by $F(t) = \eta(t)/\eta_{max}$, $K = \eta_{max}/H_i$, Z_0 is the crest height from the still water level. m is the discharge coefficient; in this study we assume that m will take the value about 0.5 according to Kikkawa et al. (1967). A definition sketch of wave overtopping together with notations used in this paper is shown in Fig.2.

Fig.2 Definition sketch of wave overtopping

To evaluate wave overtopping rate by this model, the following three quantities must be given: the ratio of maximum surface elevation and incident wave height, K , the non-dimensional time variation of the surface displacement, $F(t/T)$, and the incident wave height, H_i . In this study, we redefine η_{max} and H_c as the maximum surface elevation and the crest height of the seadikes from the mean water level as shown in Fig.2 to refine the model. Therefore, besides those three quantities the mean water level, $\bar{\eta}$, is also required.

If we can find universal expression for K and $F(t/T)$, it

becomes possible to estimate wave overtopping rate based on the weir model (Eq.(1)) provided that the incident wave height, H_i , and the mean water level in front of the seadike, $\bar{\eta}$, are given. However, it is surely a hopeless work to formulate the non-dimensional time variation of the surface displacement, $F(t/T)$, within the breaker zone.

In this study, we first calculated the value of K from Eq.(1) by using the experimental results of wave overtopping rate conducted by many researchers (Ishihara et al.(1960), Inoue et al.(1972), Kikkawa et al.(1967), Tominaga et al.(1970) and Inoue(1973)). Then, we conducted close investigations of the value of K by assuming that $F(t/T)$ varies sinusoidally.

The results are shown in Fig.3. The upper part of the figure indicates the results obtained in the cases where clapotis without breaking were formed in front of the seadike. That is the depth at the foot of the seadike was deep. The lower part of the figure shows the results in the cases where seadikes were located in the breaker zone. In the cases where no information about H_i and $\bar{\eta}$ was given, these values were estimated numerically, the detailed procedure for which is described in the following section.

Fig.3 K vs. H_c/H_i

The value of K in the clapotis region is uniquely determined by H_c/H_i and not depend on H_i/L_i where L_i is the wave length in front of the seadikes. This agrees with the results which have already pointed out by Tsuchiya et al.(1970). The solid line in the figure is the regression of K in the clapotis region. Hereafter we refer K in this region as K_c , which is

expressed by

$$K_c = 0.59H_c/H_i + 0.59 \quad (2)$$

The value of K in the breaker zone also increase with the increase of H_c/H_i and does not depend on H_i/L_i . However, some scatter can be seen when compared with K 's value in the clapotis region.

Figure 4 illustrates examples of variation of K 's value in the breaker zone with the relative location of seadikes to the wave break point to investigate the reason of the scatter of K 's value in the breaker zone (Park et al. (1987)). X_i in the horizontal axis is the relative distance between the location of seadikes and wave breaking point and is taken positive onshorewards. L_b is the wave length at the wave breaking point.

Fig.4 Variation of K with X_i/L_b

From this figure, it is found that K is constant in the region of $X_i/L_b < 0$ and $X_i/L_b > 0.5$. However, in the region of $0 < X_i/L_b < 0.5$, K increases with the increase of X_i/L_b .

The authors (Sawaragi et al. (1986)) have already pointed out that when the vertical wall is located in the region of $X_i/L_b < 0$, that is offshore of the wave breaking point, clapotis without breaking forms in front of the wall. When it is located in the region of $X_i/L_b > 0.6$, waves after breaking attack it. When the vertical wall is located in the region between $0 < X_i/L_b < 0.6$, clapotis with breaking at the loop forms. The variation of K 's value with the change of X_i/L_b appears in Fig.4 coincides with these situation of wave fields in front of the seadikes. However, the reason for the increase of K 's value in the region of $0 < X_i/L_b < 0.5$ is not found out.

A solid line in the lower part of Fig.3 is the regression line of K calculated in the cases where $X_i/L_b > 0.5$. Here-

after, we refer K in this region as K_b , which is given by

$$K_b = 0.62H_c/H_i + 0.88 \quad (3)$$

The value of K in the region where $0 < X_i/L_b < 0.5$ becomes a function of X_i/L_b and can be evaluated by

$$K = 2(K_b - K_c)(X_i/L_b) + K_c \quad (4)$$

NUMERICAL MODEL FOR THE PREDICTION OF WAVE TRANSFORMATION ON THE REEF

A series of experiments was carried out to investigate wave transformation including forced wave breaking on the reef. Based on the experimental results, numerical model for predicting wave transformation on the reef was constructed.

1) Two-dimensional experiments of the wave transformation on an artificial reef

Experiments were carried in a wave tank of 30m long, 0.7m wide and 0.9m high. An artificial reef made of polywood was placed on a model beach with a slope of 1/30. The slope of artificial reef was determined at 1/30 as suggested in the manual on the utilization of sandy beach (Port and Harbor Bureau (1979)). The offshore slope of the reef was 1/2. A sketch of the artificial reef used in the experiments is given in Fig.5 together with the notation used in the following descriptions.

Fig.5 Sketch of artificial reef used in the experiments

A water depth at a toe of the reef, h , was kept constant at 10cm and reefs of different relative heights ($h_s/h = 0.25, 0.55$ and 0.75) were used. Periods of experimental waves were $T = 0.8s, 1.1s$ and $1.4s$. Wave heights at the toe of the reef, H_i , were adjusted to be $H_i/h = 0.5, 0.5^*, 0.75, 0.75^*$ and 0.9 where $*$ indicates the case where waves had broken before they reached the toe of the reef. All the waves which reached the toe of the reef without breaking broke forcibly

on the offshore slope of the reef. A breaker type of these waves was a typical plunger.

Water surface elevations were measured with six capacitance type wave gauges at an interval of 5 to 10cm around the artificial reef. The analogue output signals were digitized at a time interval of 1/20s. Mean water levels and wave heights were calculated from these digital data. A reflection coefficient was also calculated by the method proposed by Goda(1985) to be 0.15 at the maximum.

2) Condition for forced wave breaking on an artificial reef
 When waves reach an artificial reef, they break owing to an abrupt change in water depth. In this section, the condition for wave breaking on the artificial reef is investigated by applying Goda's breaking criterion(Goda(1985), which explicitly takes into account the effect of bottom slope:

$$H_b/L_o = A[1 - \exp(-1.5(1 + 15 \tan^4 \theta) \pi h_b/L_o)] \quad (5)$$

where H_b and h_b are the wave height and the water depth at the breaking point, L_o is the deep water wave length, $\tan \theta$ is the bottom slope and A is the coefficient which will take the value between 0.12 to 0.18 for the waves that break on an uniformly sloping beach.

The applicability of Eq.(5) to the wave breaking on the artificial reef was examined by evaluating the coefficient A in Eq.(5) from measured H_b and h_b , where $\tan \theta$ was assumed to be the slope of the artificial reef(1/30). The results are shown in Fig.6. Open circles in the figure indicate the cases of offshore breaking; in these cases, the value of A shows almost constant(0.18). However, when waves break on the reef, A 's value increases with the relative height of the reef, h_s/h , as shown by closed circles in the figure. It is also seen that the value of A decreases with increasing relative water depth at the toe of the reef, h/L_o .

Fig.6 Relation between A and h_s/h

From these results, the following approximate expression is obtained under the condition of $0.25 < h_s/h < 0.75$ and $0.03 < h/Lo < 0.10$:

$$A = (-2.18h/Lo + 0.45) h/h + 0.1.7 + 0.21h/Lo \quad (6)$$

The values of A estimated from Eq.(6) are also shown in Fig.6.

3) Applicability of the bore model to the prediction of wave attenuation on an artificial reef

Some examples of wave height distributions measured in the experiments are shown in Figs.7 to 9 for the case of $T=1.1s$ and $h/Lo=0.05$. Figures 7 and 8 correspond to the cases where incident waves broke on the offshore slope of the reef or on the reef. Figure 9 represents the case where incident waves broke off the reef. In these figures, (a),(b) and (c) indicate the cases of $h_s/h=0.25, 0.55$ and 0.75 , respectively.

The decay of wave height after breaking in the figures becomes more rapid when the reef is higher regardless of the value of H_i/h .

The authors applied the bore model to predicting the wave height and mean water level on the reef. The wave height in the offshore region was calculated by using the shoaling coefficient formulated by Shuto(1974). The wave height within the breaker zone was estimated from the bore model with the energy dissipation rate proposed by Mase et al. (1982). In the calculation, equations of energy flux conservation and time and vertically averaged momentum flux and mass flux conservations were reduced to a system of difference equations and solved iteratively until the stable solutions are obtained.

The grid spacing was taken at $1/400$ to $1/800$ of the incident wave length to determine the breaking point exactly from Eqs.(5) and (6).

Calculated wave heights are shown by the solid lines in Figs.7 to 9. In the cases that the reef is relatively low ($h_s/h=0.55$), predicted wave heights agree well with the measured wave heights. When the reef is relatively high ($h_s/h=0.75$), the wave heights after breaking is slightly underestimated.

Fig.7 Wave height distributions on the reef ($H_i/h=0.5$)

Fig.8 Wave height distributions on the reef ($H_i/h=0.9$)

Fig.9 Wave height distributions on the reef ($H_i/h=0.75$)

WAVE OVERTOPPING RATE FROM THE SEADIKE ON THE REEF

Now, we can finally obtain all information to predict wave overtopping rate from the vertical seadike on the artificial reef. In this chapter, the applicability of proposed procedure for predicting wave overtopping rate on the reef is examined through experiments.

Experiments were carried out in the same wave tank as used in the experiments of wave transformations. Horizontal reefs set on the model beach with the slope of 1/30 was used and wave overtopping rate from the seadikes on various locations on the reef were measured. A water depth on the reef, h , was varied between 4cm to 8cm and experimental waves of deep water wave heights, H_o , and periods, T , between 7cm to 11cm and 1.0s to 1.5s were used. Whereas, the height of the reef, h_s , was kept constant (10cm).

Total number of experimental runs was 150 in which the relative crown height of the seadike, H_c/H_i , covered 0.3 to 2.0. The location of seadike, X_i/L_i , was varied from 0.0 to 3.0, where X_i is the distance between the shoulder of the reef and the seadike and L_i is the length of incident waves on the reef. In all the cases, all the incident waves broke forcibly on the shoulder of the reef.

Fig.10 shows the comparison between measured and calculated non-dimensional wave overtopping rate, q ,

$$q = \frac{Q}{\sqrt{g}L_iH_i} \quad (7)$$

Solid lines in the figure illustrate q estimated by Eq.(2).

From the figure, it is found that measured wave overtopping rate decreases rapidly with the increase of H_c/H_i . It is also seen that predicted q covers upper limit of measured q and increases a little with H_i/L_i .

This implies that our procedure for the prediction of wave overtopping rate from the seadike on the reef is adequate.

EFFECT OF THE ARTIFICIAL REEF ON WAVE OVERTOPPING

The applicability of our model to the wave overtopping by the irregular waves is examined by conducting experiments on the assumption of actual state. Further, the effect of artificial reef constructed in front of existing seadikes on wave overtopping in the irregular field is also discussed.

The experiments were conducted in the same wave tank as used in the former two experiments. The slope of model artificial reef was 1/30. The length of the reef, B , was 0.5, 1.0, 1.5 and 2.0m and the height of the reef, h_s , was 4.5 and 7.0cm.

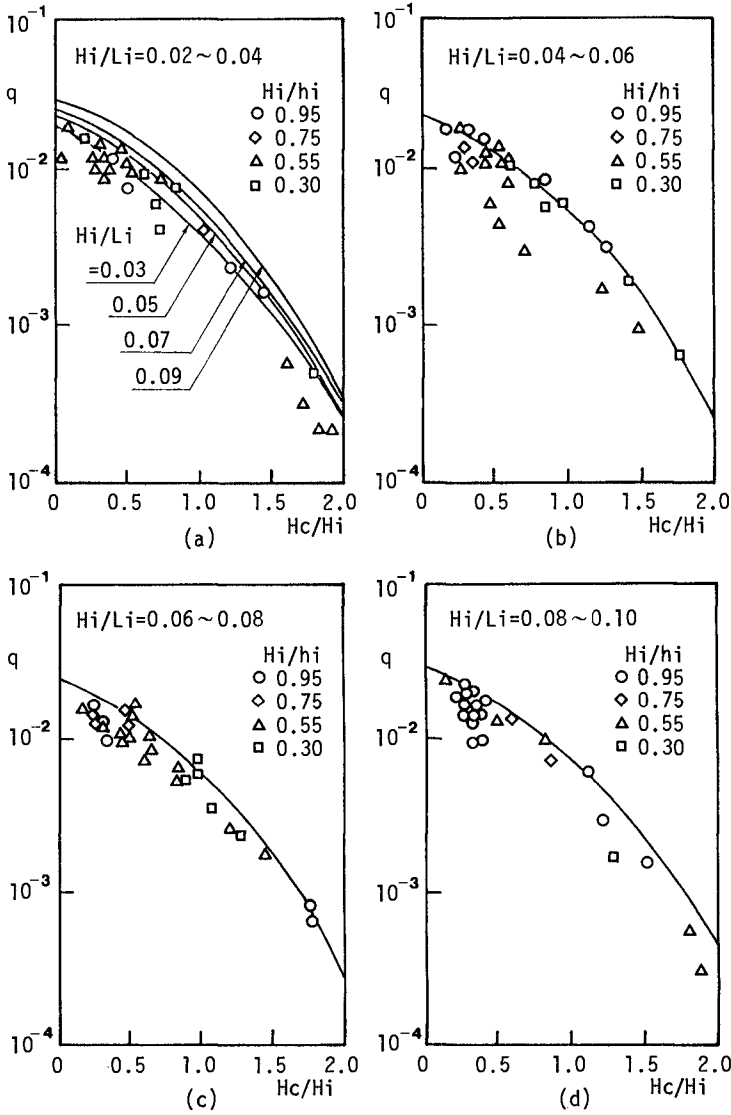

Fig.10 Non-dimensional wave overtopping rate from the
seadike on the reef

Experimental waves generated numerically to have Pierson-Moskowitz spectrum were used. Significant wave period, T_s , was 1.21s and significant wave heights, H_{s0} , in deep water were 8cm in the case of $h_s=4.5$ cm and 9.3cm in the case of $h_s=7$ cm. The crown height of the seadike, Z_0 , from the sill water level was adjusted to be $Z_0/H_{s0}=0.5-0.6$.

To predict wave overtopping rate by irregular waves, so-called "individual wave analysis method" is applied. That is, each volume of wave overtopping, q_k , brought about by individual waves which are defined by the zero-up-cross method in the irregular wave train is calculated from Eq.(2). Then, the time averaged wave overtopping rate, \bar{Q} , is estimated by summing up, q_k , as given by Eq.(8).

$$\bar{Q} = \left[\sum_k^N (q_k \sqrt{g H_k^2 L_k T_k}) \right] / \left(\sum_k^N T_k \right) \quad (8)$$

where N is the number of waves reached at the seadikes during the measurement of wave overtopping, H_k , L_k and T_k are the height, the length and the period of k -th wave. The value of q_k in Eq.(8) indicates the predicted volume of wave overtopping caused by k -th wave.

The individual wave analysis method for irregular wave transformation on the reef is applied on the assumption that there is no interaction between individual zero-up-crossing waves. This kind of analyses of irregular wave transformation on uniformly sloping beach have already been carried out by Mase et al.(1982).

As mentioned before, wave overtopping rate depends on both H_c/H_i and H_i/L_i , the joint distribution of wave height and period was given as a boundary condition at the offshore of the reef. To determine wave breaking points of individual waves, Eqs.(5) and (6) are used. Based on these results, q_k caused by each waves is calculated by using empirical expression of K (Eqs.(2)-(4)).

Fig.12 shows the comparison between measured and predicted time averaged wave overtopping rate on the reef by irregular waves. From the figure, we can judge that our model can also be applicable to the wave overtopping from the seadike on the reef by irregular waves.

Finally, Fig.13 indicates the effect of the length of the artificial reef on the reduction of wave overtopping. The vertical axis is normalized time averaged wave overtopping rate \bar{q} ($=\bar{Q}/\sqrt{gH_{s1}^2 L_{s1}}$) and the horizontal axis is the non-dimensional length of the artificial reef, B/L_{s1} , where H_{s1} and L_{s1} are the significant wave height and length in front of the seadike. From the figure, it can be seen that \bar{q} decreases rapidly in the region of $B/L_{s1} < 0.8$ and becomes almost constant beyond that range of B/L_{s1} .

Fig.12 Comparison of measured and estimated time averaged wave overtopping rate on the reef by irregular

Fig.13 Non-dimensional wave overtopping rate vs. non-dimensional length of artificial reef

When the artificial reef was constructed in front of the seadike, relatively large waves in the irregular wave train broke forcibly and number of higher waves of the wave train which reached in front of the seadike decreased. Character-

ristics of the incident waves and dimensions of the reef determine the maximum waves which can transmit on the reef without breaking. However, the number of the waves which broke forcibly on the reef decreased with the increase of the length of the reef because the depth at the shoulder of the reef became deep. In such cases, the effects of the artificial reef appears in the point that it merely decreases the depth at the foot of the seadike.

This is the implication of the change of \bar{q} shown in Fig.13. In the case shown in Fig.13, it can be said that the effective length of the artificial reef to break large waves significantly corresponds to $0.8 \cdot L_{si}$.

CONCLUDING REMARKS

A procedure for estimating a wave overtopping rate from a seadike on an artificial reef is proposed based on a weir model in an unidirectional flow by assuming that the surface displacement in front of the seadike varies sinusoidally. In the procedure, the crown height and the maximum surface elevation from the mean water level and the incident wave height in front of the seadike are required to calculate the wave overtopping rate.

Among these, an empirical expression for the ratio of the maximum surface elevation to the incident wave height is given as an increasing function of the ratio of the crown height to the incident wave height. The incident wave height and mean water level in front of the seadike can be estimated numerically by using empirical criterion for the forced wave breaking on the reef proposed in the study.

So-called "individual wave analysis method" is applicable for the estimation of the wave overtopping rate in the irregular wave field.

It is also found that when the height of the reef in front of the seadike is given, a proper length of the reef exists to reduce the wave overtopping.

CHAPTER 24

EFFECT OF BOUSSINESQ EQUATIONS ON WAVE SPECTRA PROPAGATION

J.P.Sierra, A.S.Arcilla*, J.J.Egozcue** and J.L.Monso**

ABSTRACT

A 2-D numerical model has been developed to simulate wave propagation prior to breaking. This non linear hydrodynamic model works in connection with various spectral analysis routines. This paper intends to study the propagation effects on the wave time-series and on the corresponding spectral density functions in order to gain insight on both the spectral description of waves and irregular wave propagation.

1.- INTRODUCTION

Flow properties in coastal areas are of great importance in Maritime Engineering, for the solution of numerous problems such as the desing of offshore and coastal structures, shore evolution analysis, ship motions etc. For all of these subjects, a detailed knowledge of the shallow water wave heigth and propagation direction are required. State of art wave propagation models are usually either linear or unidirectional (in the input).

However, in order to enable the characterizacion of desing wave conditions, the use of two parameters as wave height and period is not enough. Wave randomness must be considered, since the assumption of unidirectional and monochromatic waves, can lead to unacceptable results from the Maritime Engineering standpoint.

One of the best ways to describe the wave irregularity is through a spectral density function, which is able to condense easily all the information involved in a wave time-series, with different frequencies and wave heights. If the possibility of waves travelling in different directions is considered, the estimation of the directional spectrum will be necessary, in order to achieve a full description of the wave characteristics.

Although spectral analysis has been widely used for several decades, a non linear model has been seldom coupled with spectral models.

In this paper a 2-D numerical non linear model for the simulation of wave propagation prior to breaking is described. In this model, both regular and irregular wave trains can be used. The propagation effects on the wave time-series and on the spectral density function are studied, in order to gain insight on both the spectral description of waves and irregular wave propagation.

2.- WAVE PROPAGATION

The numerical model is based on Boussinesq-type equations, in which the vertical velocity of the fluid particles is supposed to increase linearly from zero at the bed to a maximum magnitude at the free surface. The Boussinesq equations are formulated in terms of vertically-integrated mass and momentum conservation laws and are obtained with a perturbation technique (S.Arcilla and Monso, 1985), yielding the following expressions (Peregrine, 1967).

- Continuity equation

$$\frac{\partial H}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0 \tag{1}$$

- x-momentum equation

$$\begin{aligned} \frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left(\frac{p^2}{H} \right) + \frac{\partial}{\partial y} \left(\frac{p \cdot q}{H} \right) + gH \frac{\partial(H-h)}{\partial x} = \\ \frac{Hh}{2} \left[\frac{\partial^3 \left(\frac{hp}{H} \right)}{\partial t \partial x^2} + \frac{\partial^3 \left(\frac{hq}{H} \right)}{\partial t \partial x \partial y} \right] - \frac{h^2 H}{6} \left[\frac{\partial^3 \left(\frac{p}{H} \right)}{\partial t \partial x^2} + \frac{\partial^3 \left(\frac{q}{H} \right)}{\partial t \partial x \partial y} \right] \end{aligned} \tag{2}$$

-y-momentum equation

$$\begin{aligned} \frac{\partial q}{\partial t} + \frac{\partial}{\partial x} \left(\frac{p \cdot q}{H} \right) + \frac{\partial}{\partial y} \left(\frac{q^2}{H} \right) + gH \frac{\partial(H-h)}{\partial y} = \\ \frac{Hh}{2} \left[\frac{\partial^3 \left(\frac{hp}{H} \right)}{\partial t \partial x \partial y} + \frac{\partial^3 \left(\frac{hq}{H} \right)}{\partial t \partial y^2} \right] - \frac{h^2 H}{6} \left[\frac{\partial^3 \left(\frac{p}{H} \right)}{\partial t \partial x \partial y} + \frac{\partial^3 \left(\frac{q}{H} \right)}{\partial t \partial y^2} \right] \end{aligned} \tag{3}$$

Where $H = h + \eta$

h is the still water depth

η is the free surface elevation

$p = \int_{-h}^{\eta} u \cdot dz$ is the mass flux along the x axe.

$q = \int_{-h}^{\eta} v \cdot dz$ is the mass flux along the y axe

u, v are the particle velocities along the x,y, axes.

Other terms can be easily included in these momentum equations, (S.Arcilla and Monso, 1986). With these additional terms, (e.g.Coriolis acceleration, wind friction, turbulent viscosity or bottom friction) a large number of physical phenomena can be adequately reproduced by the model.

The momentum conservation laws are highly non linear differential equations, and they include a third order derivative term, which is due to the existence of a constant vertical acceleration.

The vertical integration of equations (1),(2) and (3) reduces the problem from three to two independent dimensions. These equations are suitable for a wide range

of wave lengths. In particular, short wind waves in shallow water provide an acceptable ratio of water depth to wave length except for the shortest waves. These waves can be thus considered as long waves, and their propagation can be correctly simulated by the model.

The behaviour of different kinds of waves can be characterized by Ursell's parameter (UR).

$$UR = \eta \frac{L^2}{h^3} \quad (4)$$

Boussinesq equations ($UR = O(1)$) degenerate into de linear long-wave equations ($UR \ll 1$) or the Airy equations ($UR \gg 1$) with certain additional errors (S. Arcilla et al., 1985). This means that a single model, based on Boussinesq-type equations may be used to cover the whole range of physical problems (provided the associated errors are acceptable). When waves are of finite amplitude, the ratio h/L is small and breaking does not occur.

Considering different terms of the momentum equations and varying initial and boundary conditions, it is possible to reproduce a wide variety of physical phenomena such as Kelvin waves, storm surges, solitary waves, refraction, reflexion, diffraction, bottom friction, etc.

The equations are solved by means of an implicit centered finite-differences technique with variables defined on a space staggered rectangular grid. A double-sweep algorithm (Abbott and Ionescu, 1967) is invoked for solving the system avoiding large and expensive matrix inversion operations.

The truncation errors are of second order in time and space, i.e. $T.E. = O(\Delta x^2, \Delta y^2, \Delta t^2)$. The numerical scheme is conditionally stable and convergent. The propagation model is valid and yields reasonable results when $h/L < 0.2$. This means that the model can be applied in shallow or intermediate water depth but not in deep water.

Figure 1. Sinusoidal long wave propagation

In open boundaries, an absorbing-reflecting boundary condition (S. Arcilla et al., 1986) is used. In this way, the multiple reflections due to innerly reflected waves are avoided, because these reflected waves are allowed to escape the domain unhampered.

The model was first calibrated in its linear version. Here, the momentum equations only include the local acceleration and the linear part of the pressure gradient term.

Figure 1 shows the application of the model for a sinusoidal long wave propagation. The characteristics of the discretization were $\Delta x = 200 \text{ m.}$, $\Delta y = 200 \text{ m.}$ and $\Delta t = 5 \text{ s.}$

The wave parameters were : Wave amplitude $a=1 \text{ m.}$, wave period $T=300 \text{ s.}$, wave length $L=9389 \text{ m.}$ and the depth was $h=100 \text{ m.}$

The figure shows a good agreement between the numerical model results and the analytical solution.

Another test was made for sinusoidal short waves in shallow water. The characteristics of the discretization were $\Delta x = 3 \text{ m.}$, $\Delta y = 3 \text{ m.}$ and $\Delta t = 1 \text{ s.}$

and the wave parameters were Wave amplitude $a=1 \text{ m.}$, wave period $T=18 \text{ s.}$, wave length $L=125 \text{ m.}$ in a depth of $h=5 \text{ m.}$

Figure 2. Sinusoidal short wave in shallow water propagation

Figure 2 shows that as the wave progresses the quality of the results decreases, although the fit between numerical and theoretical solutions is relatively acceptable. The poor quality of the results is obviously due to the fact that linear theory is not valid in shallow water.

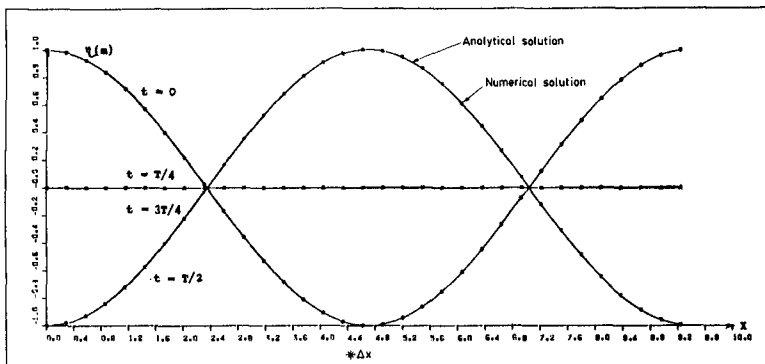

Figure 3. Reflection of a sinusoidal wave

Once the model had been tested for wave propagation, tests were made for reflecting waves, comparing computed results with the theoretical solution. Figure 3 shows the reflection of a sinusoidal wave on a vertical wall with constant water depth, forming a stationary wave.

The discretization and wave characteristics are the same as in the example showed in figure 1. The fit at different instants of time, between numerical and analytical results is excellent.

Figure 4. Illustration of model accuracy for different Courant numbers

Finally, phase and amplitude portrait errors were analysed. As an example, figure 4 shows the ratio of numerical celerity to theoretical celerity vs the number of points per wave length for different Courant numbers. It is seen that, for $Cr=1$, an acceptable accuracy is obtained with values of $N/L > 20$. When the Courant number increases, it is difficult to get a similar accuracy though more points per wave length are used.

Figure 5. Solitary wave propagation

After the linear version was calibrated, the non linear model was tested with cnoidal wave theoretical solutions, using equations (1), (2) and (3). The analytical solution of these equations, that exclude frictional stresses, Coriolis accelerations and similar terms, is the solitary wave. Figure 5 demonstrates the good fit between

numerical and theoretical results after 24 seconds. The discretization characteristics were $\Delta x = 2.5 \text{ m}$, $\Delta y = 2.5 \text{ m}$. and $\Delta t = 0.25 \text{ s}$.

and the wave parameters were wave height $H_0 = 1.5 \text{ m}$, depth $h = 5 \text{ m}$.

3.- SPECTRAL MODELS

In scalar spectral analysis, numerous models exist for time series generation and processing. These models are based on different techniques and may be divided in two groups:

- Conventional methods, based on the Fast Fourier Transform (FFT) algorithm (Cooley and Tukey, 1965).

-Parametric methods, involving autoregressive (AR) and autoregressive-moving average (ARMA) models.

Every technique presents several advantages and inconvenients with respect to the others. Therefore, the selection in every case of the most suitable algorithm will be necessary. For improving the use of design spectra in Maritime Engineering, several pattern spectra have been introduced in last decades. These spectra depend on various parameters. Fitting the parameters to the local conditions, a representative spectrum is obtained. The Pierson-Moskowitz spectrum (Pierson and Moskowitz, 1964) and the JONSWAP spectrum (Hasselmann et al.,1973) are the most well-known ones. However, the two formulations are only accepted in deep water. In shallow water, the use of suitable spectra as TMA spectrum (Bouws et al.,1983) is needed.

An example of the use of scalar spectral analysis techniques, in which the time series is generated from a JONSWAP spectrum through an ARMA(8,1) model, is showed in figure 6. The parameters of the JONSWAP spectrum were $\sigma_u = 0.07$, $\sigma_b = 0.09$, $\alpha = 0.03$, $\gamma = 3.3$ and $\omega_m = 0.18$

Figure 6. Time series generated from a JONSWAP spectrum

In figure 7, three spectra are plotted. They belong to the initial JONSWAP spectrum, the theoretical spectrum calculated from the autocorrelation function corresponding the JONSWAP, and the spectrum evaluated from the time series simulated. The agreement between the three spectra is remarkable, showing the validity of the time series generation technique.

On the other hand, the determination of the directional spectral density function $S(\omega, \theta)$ is made by recasting the function as

$$S(\omega, \theta) = S(\omega) \cdot D(\omega, \theta) \quad (5)$$

with

$$\int_0^{2\pi} D(\omega, \theta) \cdot d\theta = 1 \quad (6)$$

where $S(\omega)$ is the scalar spectral density function, computed using one of the aforementioned methods, and $D(\omega, \theta)$ is the directional spreading function. A convenient approximation to this function may be obtained by expanding $D(\omega, \theta)$ as a Fourier series as

$$D(\omega, \theta) = \frac{1}{\pi} \left[\frac{1}{2} + \sum_{n=1}^{\infty} (a_n \cdot \cos n\theta + b_n \cdot \sin n\theta) \right] \quad (7)$$

a_k, b_k are Fourier coefficients

Figure 7. Spectral density functions of the time series generated

Measurement of directional waves in Nature are rather difficult. For this purpose, the pitch-roll buoy is one of the most extended instruments nowadays. This device provides three time series corresponding to the free surface elevation $\eta(t)$, and the wave slopes in two perpendicular directions $\eta_x(t)$, $\eta_y(t)$. Having time series of three canals, just the two first Fourier coefficients can be computed only.

For the estimate of the directional spectrum, the way to be followed involves three steps :

- i) Determination of the cross spectra between the time series
- ii) Computation of the Fourier coefficients for different frequencies.

iii) Interpolation of the directional spectrum. This last step may be carried out by two ways. The first is fitting the directional spectrum to prefixed distribution functions. The second is the rational interpolation through AR and ARMA models. The latter was tested with 10 directional wave records obtained in the North Sea the 1-12-1983 and provided by the Programa de Clima Marítimo of the Ministry of Public Works (MOPU) in Spain. These time series were recorded at intervals

of 3 hours on a well developed sea with a wind direction of $250 - 260^\circ$ for the first series. The wind direction changes to 0° in the tenth series, producing a change in the wave direction for the high frequencies.

Figures 8 and 9 show the wind and wave mean direction for the first and the tenth records.

Figure 8. Wind and wave mean direction. Series 1

Figure 9. Wind and wave mean direction. Series 10

The directional spectra from these records (with three time series $\eta(t)$, $\eta_x(t)$, $\eta_y(t)$ in every record), were determined using rational interpolation through AR and ARMA models. In figures 10 and 11, the directional spectrum modes, i.e. the predominant directions, for every frequency are plotted. The results show a good reproduction of the mean direction in the directional spectra calculated.

The use of rational interpolation gives an additional advantage, since it is very easy to reverse the procedure and given a directional spectrum to generate a record. This record will be composed of three time series corresponding to the free surface elevation $\eta(t)$ and other two parameters, such as the wave slopes $\eta_x(t)$, $\eta_y(t)$. Nevertheless, these two parameters may be replaced for others if the transference function is changed.

4.- WAVE TIME-SERIES PROPAGATION

As it has been showed in section 2, the present model reproduces closely the different phenomena involved in the regular wave trains propagation. In the case of irregular waves, it would be necessary to determine each parameter from the field data or calibrate them with physical models. Both possibilities, are out of the scope of this work. Because of the difficulty of handling large wave records, the authors have assumed their representation by means of the spectral density function. Therefore, when random waves are used, the calibration of the model is done assuming the invariability of the spectrum when waves travel on a constant deep area and without obstacles that could interfere their propagation.

Figure 10. Predominant directions in directional spectrum. Series 1

Figure 11. Predominant directions in directional spectrum. Series 10

A time series generated by means of one of the aforementioned techniques was propagated using the Boussinesq model, over a fluid domain with horizontal bottom and with a depth of 5 m. The result was another time series. As the visual comparison between the two time series is very difficult, their characteristics have been confronted computing the spectral density functions, that are showed in figure 12. The plots of these functions are practically identical and therefore it implies that the numerical model reproduces accurately the irregular wave propagation, over a horizontal bottom.

Another case analysed was the refraction of irregular wave over an uniform slope. Figure 13 presents the spectral density functions of the time series before and after the refraction. In this plot it is shown that the peak period is the same, but refraction produces a secondary peak with a frequency that is nearly twice the peak frequency. Then refraction produces a transference of energy towards higher frequencies, keeping the peak period but decreasing the mean period.

Figure 12. Spectra of the generated and propagated time series

Figure 13. Spectral density functions of the initial and refracted time series

Moreover the study of the diffraction of irregular waves was carried out. In this study, a linearized version of the numerical model was employed. In figure 14, the fluid domain is illustrated. The boundary with the gap is a vertical wall. The other boundaries are open, to avoid reflections. In the points A,B,C, and D, the free surface elevation was recorded. When the time series were obtained, the spectral density functions were determined and compared with the spectral density function of the initial time series, as it is showed in figure 15. The analysis of these figures shows logical results because the greater the distance to the gap is, the smaller the area comprised below $S(\omega)$ is, i.e. the energy of the spectrum decreases when the point is far away. On the other hand, the peak frequency does not change after diffraction in all points inside the fluid domain, though this circumstance can be due to the use of a linearized version of the propagation model.

Finally, a real example has been analysed. Here, the lay-out and the bathymetry are the ones corresponding to a Spanish harbour. Figure 16a represents the input wave spectrum used at the entrance of the harbour. This spectrum has been derived from field measurements.

Figure 14. Diffraction study. Fluid domain.

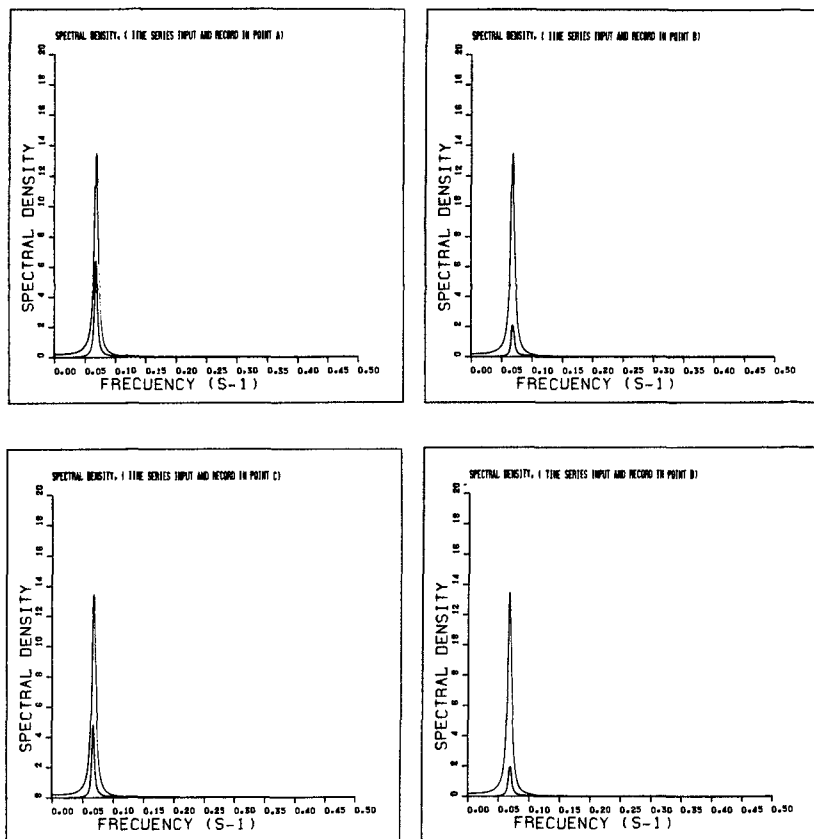

Figure 15. Spectral density function before and after diffraction.

Figure 16b shows the result of carrying out an ARMA spectral process of the surface elevation time series, obtained after a run of the propagation model, inside a basin of the harbour. This output wave spectrum has a secondary peak in the origin. Since the spectrum has been plotted with 100 points, the secondary peak means that a long wave with a period up to 200 seconds is present in the time series recorded by the numerical model inside the basin. Actually similar wave conditions to those of the numerical simulation gave way to the record of long waves with a period of 240 seconds in the same basin. Therefore, the propagation model allows simulating and discovering long wave phenomena in real cases.

Figure 16. Input and output wave spectrum.

5. CONCLUSIONS AND FUTURE PERSPECTIVES

The main conclusions of this paper are

- The wave propagation numerical model simulates accurately the propagation of regular and irregular waves in a wide range of conditions. The model behaviour has proved to be satisfactory for the usual values of the control parameters. The main exception is the breaker zone, in which the wave height is an important fraction of the water depth. However, the third order (truncation error) scheme which is now being developed, is expected to provide improved results in these cases.

- With a given $S(\omega)$, a time series $\eta(t)$ can be simulated. This signal can be used as a model input. After the run of the propagation model, the result will be another time series $\eta^*(t)$, which conveniently processed will give way to another spectral density function $S^*(\omega)$.

- With a given directional spectrum $S(\omega, \theta)$, a record with three time series ($\eta(t)$, $\eta_x(t)$, $\eta_y(t)$ for example) can be simulated, and conversely, three time series let the directional spectrum to be obtained. Up till now, the propagation model does not accept three time series as input, though it can yield these three signals as output. The efforts are now concentrated in getting the directional wave as the input of the model. In this case, a $S(\omega, \theta)$ could be the incoming one to the model, and another directional spectrum $S^*(\omega, \theta)$ could be the outgoing one.

- Numerical simulation with Boussinesq equations is an useful tool for the spectral determination and the analysis of the spectral evolution in shallow water when waves are travelling. The model has been applied successfully to real cases. With the coupling between the Boussinesq model and the spectral techniques developed in this paper, it is possible to obtain a more compact and coherent

information on irregular wave propagation in coastal zones, bays and harbours, taking into account non-linear propagation effects.

CHAPTER 25

The Influence of Currents on Wave Attenuation

Richard R. Simons 1
Anthony J. Grass 2
Andreas Kyriacou 3

Measurements have been made of wave height decay in a rough bottomed flume for waves alone and for waves combined with 3 following currents. Tests have also been carried out to quantify energy dissipation at the sidewalls under these conditions. Results show that waves attenuate less rapidly when propagating on a following current, with a corresponding reduction in wave-current friction factor. A simple method is suggested by which wave attenuation in the presence of following and opposing currents can be predicted.

Introduction

Coastal Engineering is dependent on a detailed knowledge of wave climate for the design of coastal structures and defences, and in the prediction of sediment transport. An important step in obtaining this information is to transform available offshore wave data for application to coastal conditions. This procedure has to take into account shoaling, depth refraction, diffraction, frictional energy losses, and the action of currents. Apart from additional refraction, currents have two other important effects on waves. The first is that as the waves propagate onto a region of flowing water they experience a change in wave length, height, and orbital velocity distribution. These changes are local and to some extent reversible. The second effect is that the shear stress at the seabed, and hence the rate of wave energy dissipation, is altered significantly. This causes a permanent change which propagates with the waves until they break on the shore.

A number of papers describing field observations (i.e. Battjes, 1982) have commented that wave heights often increase when waves are propagating on a following current, and, conversely, that they decrease in the presence of an

opposing current. At first sight, these effects are anomalous in that all theories of "local" wave-current interaction predict that the stretching effect of a following current on waves reduces their height. However, a possible explanation is provided by the results of Kemp and Simons (1983), who found that attenuation rates go down if waves propagate with a following current, but that attenuation increases when waves move onto an opposing current. Data showing similar trends have also been published by Brevik and Aas (1980) and Asano et al (1984).

The purpose of the research described in this paper is to provide more experimental data for the precise determination of wave attenuation and boundary shear stresses under combined waves and currents, and to suggest a simple method by which the observed results can be predicted for any particular relative current strength in terms of a wave-current friction factor.

Experiments

The main set of tests were performed in a flume 610mm wide and 30m long, with a still water depth of 300mm. The sides of the flume were of smoothly painted wood, incorporating glass windows at regular intervals. The bed was evenly covered with a single layer of 10mm angular limestone chippings, producing a Nikuradse roughness of approximately 25mm, close to that found in the work of Kemp and Simons (1983). These large roughness elements had a critical velocity in excess of 1m/s, and thus remained immobile without the need to be glued down under any of the conditions considered in the present study.

Waves were generated by a flap-type paddle supported from above and pivoted about a point below bed level. This arrangement allowed the recirculating current flow to pass beneath the paddle within the existing channel cross section, although it was found necessary to install a duct to carry the flow downstream of the paddle before combining the current with the waves. An 0.5m length of chicken wire acted as an excellent filter for unwanted waves and turbulence in this region. At the far end, the beach was constructed of a light metal framework covered with 25mm thick permeable sheets of a woven nylon. It sloped at 6° to the horizontal.

Preliminary velocity measurements were made with a propeller meter at positions along and across the flume to determine the influence of secondary flow cells, sidewall boundary layers, and the developing bottom boundary layer. These tests were carried out for the currents alone and for combined waves and currents, taking care to reject unreliable measurements in regions where the flow was subject to reversal. The detailed velocity field was measured at a section midway along the test length of the flume using a single channel laser Doppler anemometer (LDA). This provided mean velocities, turbulence intensities, and orbital velocities at up to 30 points through the vertical, the measurements being concentrated in the highly turbulent nearbed layer. The

distribution of Reynolds stress was obtained from a two-channel LDA and used to establish the mean bed shear stress.

Wave attenuation and changes in mean water level were measured by resistance type wave probes traversed in 100mm steps through four 2m blocks spaced out along a 22m length of the flume. This made it possible to identify the pattern of reflected waves and to fit an exponential decay curve through the underlying incident wave heights.

The tests were conducted in a water depth of 300mm, using wave periods of 0.7s and 1.0s; such waves fall into the "intermediate" classification, with D/L of 0.40 and 0.22 respectively. Four wave heights were investigated for each period, giving bed orbital velocities in the range 10mm/s to 70mm/s. Scaled against the large bed roughness used in these tests, the relative bed orbital amplitude, a/k_s , was generally less than unity. Four different current conditions were considered in combination with these waves, namely, no current, and following currents with mean-over-depth velocities of 75mm/s, 190mm/s and 250mm/s. The test parameters are set out in Table 1.

Results

Hydrodynamics:

Before considering the effects of currents on the wave surface properties, it is worth noting that the hydrodynamics of the combined waves and currents were very much as found in preceding studies of a similar nature (i.e. Brevik and Aas, 1980; Kemp and Simons, 1983). For each of the three steady currents, the mean velocity profiles showed that there was a clearly identifiable logarithmic region whose slope was increased by the superposition of waves of increasing height. This implied an increase in mean bed shear stress, and also of apparent bed roughness calculated from the z_0 zero velocity intercept, when waves were added. A comparison between these results and the predictions of a number of mathematical models has recently been presented by Simons et al, (1988). It should be noted that the results were based on von Karman's constants in the range 0.33 to 0.35. These values of κ , significantly less than the classical figure of 0.4, were calculated from bed shear stresses derived from the direct Reynolds stress measurements.

With the waves propagating through still water, without any current, orbital velocities were closely described by 2nd order Stokes wave theory down to the edge of a very thin boundary layer, reflecting the low a/k_s ratios under consideration. However, the addition of a turbulent current produced a significant increase in wave boundary layer thickness - see figure 1. Reynolds stresses were also changed under the combined flow conditions: whereas for the currents alone there was a linear decrease from the maximum value at the bed out to the edge of the boundary layer, when the waves were added $\overline{u'v'}$ actually decreased in the nearbed region, producing a maximum at the outer edge of the

logarithmic layer, some 35mm above the bed.

Sidewall Tests:

The objective of the main test programme was to investigate the rate of attenuation of waves propagating over a following current, and to compare the results with those from waves in still water. The tests were carried out in a relatively narrow laboratory flume, and in order for the results to be applicable to real sea conditions it was necessary to take into account the energy dissipation at the flume sidewalls. For the case of waves alone in a smooth walled channel, Hunt (1952) presented a theory apportioning dissipation between bed and sidewalls for any chosen aspect ratio. Wave height decay was shown to be exponential, in the form: $H = H_0 e^{-\alpha x}$, with the attenuation coefficient, α , given as:

$$\alpha = \frac{k}{B} \sqrt{\left(\frac{TV}{\pi}\right) \left(\frac{Bk + \sinh 2kD}{2kD + \sinh 2kD}\right)}$$

Here, B is the channel width, D the depth of water, and k the wave number, $2\pi/L$. A similar empirical formula based on dimensional analysis was later suggested by Treloar and Brebner (1970). However, the application of theories of this type to the case of combined waves and currents has not before been considered. Thus it was decided to carry out a short series of tests to quantify the influence of the sidewalls under the present conditions, and to establish whether the Hunt theory formed the basis for an appropriate correction technique.

A temporary vertical wall of plate glass was installed over a 6m length of the flume, parallel to one of the sidewalls and such as to leave a closely uniform gap of just 10mm. Waves propagating in 300mm of water through this narrow channel attenuated rapidly, due almost entirely to frictional dissipation at the sidewalls. Figure 2 shows a typical exponential decay of wave heights for one of the tests with no current present, indicating that the Hunt theory predicts the attenuation coefficient to well within 15%, although with a consistent trend to underpredict. The modified form developed by Treloar and Brebner produced values even lower. Similar results were found when the tests were repeated with the gap reset to 20mm.

For the tests in combined waves and currents, it was impossible in such a narrow channel to reproduce the detailed characteristics of the stronger currents found in the full-width flume, although acceptable correlation was achieved with the weaker current mean velocity. Despite the reflected wave pattern being amplified by the addition of the current, the results from these tests (figure 3) showed that the sidewall attenuation was reduced by approximately 15% from that for the waves alone. In this case, taking the sidewall contribution from the corresponding wave alone tests to be between 35% and 50% of the total dissipation, use of the wave alone sidewall correction produced an error of 6%. For the

Fig.3: Wave Decay under the Influence of Smooth Sidewalls:
 $T = 1.0s$; $D = 300mm$; $u = 70mm/s$; gap = 20mm.

present work, this was felt to be acceptable.

Attenuation:

Results from the main tests in the 610mm wide flume showed that wave heights reduced exponentially along the flume both with and without currents flowing. However, attenuation coefficients were found to decrease systematically when following currents of increasing strength were superimposed (figure 4). The same effect was found both for the waves of 0.7s and 1.0s period, and it confirmed the earlier observations of Kemp and Simons (1983), who had furthermore reported that attenuation increased when an opposing current was introduced. These observations, made in a fixed frame of reference, are relevant to those predicting wave heights under real sea conditions. However, even when expressed in terms of wave height loss per wave length, or of loss of wave action (wave energy divided by relative angular frequency), there was still a clear trend for the currents to reduce the rate of change in all the tests carried out. The possibility was examined that the changes in wave height might be the result of variations in mean velocity profile over the 22m test length of the flume rather than of modified energy dissipation. However, the preliminary velocity measurements showed that any influence of the developing boundary layer, and in particular a gradual increase in surface velocity, would tend to increase apparent attenuation and hence oppose the observed effect.

In order to simplify the presentation of the results, it was decided to follow the method first proposed by Jonsson (1966) and reassessed by Brevik and Aas (1980), and to express the attenuation rates in terms of a wave-current friction factor, f_{wc} , assumed constant through the wave cycle. Neglecting the phase difference between the flow in the oscillatory boundary layer and that in the outer region, the bed shear stress is related to f_{wc} as follows:

$$\tau_{wc} = 1/2 \rho f_{wc} |\bar{u} + u_b| \cdot (\bar{u} + u_b)$$

where \bar{u} is the depth averaged mean velocity and u_b the amplitude of the oscillatory wave-induced velocity, taken to be sinusoidal, just above the wave boundary layer. Assuming that the flow is not current dominated, the Momentum Equation,

$$dF/dx + \tau_{wc} = 0, \quad (1)$$

with $F = 1/8 \rho g H^2 (2c_{gr}/c - 1/2) + \rho D u^2 + 1/2 \rho g D^2$

and $c_{gr} = c_{ga} - u$ then becomes:

$$1/4 \rho g H \frac{dH}{dx} (2c_{gr}/c - 1/2) + \rho g D \frac{dD}{dx} + 1/2 \rho f_{wc} |\bar{u} + u_b| \cdot (\bar{u} + u_b) = 0 \quad (2)$$

The averaged Energy Equation can be treated in a similar way to give:

Fig.4: Wave Height Attenuation along the Main Test Flume.

$$\frac{1}{4} \rho g H (c_{gr} + 2c_{gr}/c + 1/2) u + \rho g D u \frac{dD}{dx} + \frac{1}{2} \rho f_{WC} |\mu + u_b \cos \omega t|^3 = 0 \quad (3)$$

Eliminating the water surface slope dD/dx between (1) and (2), we are left with a relationship between wave height attenuation and f_{WC} in the form:

$$f_{WC} = \frac{gH/2\beta (c_{gr} + u) dH/dx}{|\mu + u_b \cos \omega t| \cdot (u + u_b \cos \omega t)} \quad (4)$$

$$\text{where } \beta = \frac{u \cdot |\mu + u_b \cos \omega t| \cdot (u + u_b \cos \omega t)}{|\mu + u_b \cos \omega t|^3} \quad (5)$$

It must be emphasised that this derivation relies on the assumptions of 1st order waves, a time-invariant friction factor, significant wave action relative to the current strength, neglect of phase shifts between orbital velocities and bed shear stress, and a uniform mean velocity profile.

Considering first the results for waves alone, it was found that the friction factor continued to increase for the smaller waves as the bed orbital amplitude was reduced - see figure 5. Values agreed closely with the expression given by Jonsson (1966), and also with the trends predicted by Kajiwara (1968) and Kamphuis (1975). In contrast, the addition of following currents caused a steady decrease in friction factor as the current strength was increased, with f_{WC} for very low bed orbital amplitudes tending towards the value of 0.01 determined from the current only tests. However, this behaviour became less pronounced for the larger waves ($a/k_s > 1$). Figure 5 also includes the results from the tests of Kemp and Simons (1983) where the current opposed the waves. It is interesting to note that in this case, despite the increase in observed attenuation rates when the currents were added, the corresponding friction factors were actually less than those for waves alone. This apparent anomaly was caused by the reduction in absolute wave group velocity in (4) proving more significant than the increase in attenuation dH/dx . The ratio of current strength to wave orbital velocity (u/u_b) for these tests was similar to that for the weakest following current series in the present tests, and the values of f_{WC} produced by these two very different sets of conditions agreed remarkably well with each other. This suggests that the variation in f_{WC} with relative bed orbital excursion can be characterised by a series of curves, each representing a particular relative current strength. A similar set of curves can also be generated if f_{WC} is plotted against Reynolds number (as in figure 6).

While at first sight it might seem surprising that friction factors should decrease as current strength is increased, the effect is predicted qualitatively by mathematical models of wave-current interaction such as Christoffersen and Jonsson (1985). Friction factors calculated from these models fall off from the wave alone curve for values of a/k_s less than 30, although not to such an extent as observed in the present study. The values of f_{WC} so calculated are also insensitive to the direction of the current, whether it propagates with or

Fig.5: Variation of Friction Factor, $f_{w,WC}$, with relative bed orbital amplitude, a/k_s , for different current strengths.

Fig.6: Variation of Friction Factor, $f_{w,WC}$, with Oscillatory Reynolds Number, $a u_b/\nu$.

against the waves, once again agreeing with the present observations.

Conclusions

An estimate of wave height attenuation for combined wave and current flows can be obtained for given bed roughness, relative current strength, and relative bed orbital excursion either by use of an empirical friction factor diagram or from one of the many mathematical models for wave-current interaction. A possible procedure might be as follows:

1. Calculate β from (5);
2. Derive f_{wc} from Christoffersen and Jonsson (1985);
3. Use Eqn.(4) to calculate dH/dx , and hence derive the attenuation coefficient α .

For a following current, the attenuation will be reduced with increasing current strength, but for the opposing current case the attenuation might increase or decrease, depending on the relative changes in f_{wc} and $(c_{gr} + u)$. A decrease is likely only if the current is very strong relative to the wave group velocity, with the possibility in the extreme case of a negative attenuation rate, growth in wave height, and eventual breaking.

CHAPTER 26

Some Characteristics of Breaking Waves by

Fredric Raichlen¹ and Panos Papanicolaou²

INTRODUCTION

In recent years there has been a surge in coastal engineering research devoted to various aspects of breaking waves including their kinematics at and after breaking. For a review of certain aspects of this field the interested reader is referred to Peregrine (1983) and Battjes (1988); in this discussion only certain publications pertinent to this investigation will be mentioned briefly.

With the advent of laser-Doppler velocimetry (LDV) a number of investigators have measured the internal velocities of waves both before, at, and after breaking. For example, Nadaoka (1986) measured the velocities in the shoaling region under periodic breaking shallow water waves. This extensive study of the nearshore regions resulted in vector diagrams which described very well several spatial aspects of the flow shoreward of breaking. Skjelbreia (1987) also used LDV techniques to define the kinematic characteristics of breaking solitary waves. Measurements were made of the water particle velocities under spilling and plunging breaking waves both very near breaking and after breaking, close to the water surface and to the bottom. A high degree of reproducibility was possible with the laboratory wave generation system used so experiments were conducted at different locations with essentially the same wave; this will be discussed more fully later. Skjelbreia (1987) also presented vector diagrams of the velocities under plunging and spilling solitary breakers. These measurements when compared to those of Nadaoka (1986) raise several questions regarding similarities and differences between breaking oscillatory waves and waves of translation. In addition to detailed kinematic measurements, a macroscopic view of shoaling solitary waves was also taken by Skjelbreia (1987) yielding results on the variation of the wave height with distance both before and after breaking. Although there has been a considerable amount of work along these lines in the past, observations of the changes in the wave at and after breaking are still quite useful in developing an overall understanding of the breaking process.

Other investigators have presented experimental and analytical studies dealing with waves in the regions at and just after breaking. For example, Horikawa and Kuo (1966) presented the results of experiments on the change in height of periodic waves after breaking. They, Dally et al (1984), and others used these data to compare to analytical approaches to this problem with some degree of success. Svendsen et al (1978) and Svendsen (1984) also gave attention to the decrease in wave height which was associated with wave breaking and the subsequent propagation of the broken wave. Svendsen et al (1978) have defined several different regions after breaking to describe the wave characteristics in the surf zone: an outer region where there is a rapid change in wave shape, an inner region where changes are slow and the front part of the wave resembles a periodic bore, and the region of runup of the wave on the beach. The concept of the

changing wave shape as an important aspect of the decrease of wave height after breaking was discussed by Svendsen (1984). In this connection it was suggested by him that a smaller percentage of the decrease in wave height after breaking is due to energy dissipation associated with the roller formation at breaking (and the concomitant turbulence generated) compared to that due to the change in the shape of the wave, i.e., the general collapse of the wave with distance after breaking. Svendsen (1984) applied estimates of the roller size measured by Duncan (1981), who formed a breaker behind a towed hydrofoil, to the question of the energy dissipation in a breaking wave; this will be discussed more fully later.

For some years simplified solitary wave models have been used for estimates of the characteristics of periodic breaking waves. In this paper several characteristics of breaking solitary and cnoidal waves will be discussed and contrasted to assist in evaluating the adequacy of such models. In that regard, of interest were the change in wave height and wave shape with distance and the growth and decay with distance of the roller generated at breaking for these two types of waves. The latter was given attention because of the relation between the roller characteristics and the vorticity generated in the post breaking region by the wave at breaking. For both solitary and cnoidal waves some comparisons will be made between the characteristics of spilling and plunging breakers. Experiments were conducted in the laboratory using breaking solitary and cnoidal waves with the data collected from detailed visual observations. Thus, a comparison of these waves will be made in a macroscopic context only. The experimental equipment and techniques used will be presented first followed by the presentation and the discussion of the results.

EXPERIMENTAL EQUIPMENT

A tilting wave tank was used for all experiments; the tank is 39.6 m long, 1.1 m wide, and 0.61 m deep and is constructed with glass sidewalls throughout and a stainless steel bottom which is plane to within about ± 1.0 mm. The tank is supported at a central hinge point with two motorized jacks upstream and two downstream, geared to operate together thereby permitting a continuous adjustment of slope from horizontal to a maximum slope of about 1:50. The supports for a bulkhead wave generator located at one end of the tank are an integral part of the wave tank structure and tilts with the tank; in this manner waves can be produced on a slope and caused to break at predetermined locations.

The generator is driven by an electro-hydraulic servo-system with the voltage time history determined so the velocity of the wave plate, at a given time, matches the water particle velocity of the wave as it propagates away from the plate. This wave generation technique has been described by Goring and Raichlen (1980). An iterative procedure can be used to compensate for the dynamics of the mechanical hydraulic system; see Skjelbreia (1987). The general characteristics of solitary waves generated in this tank when horizontal have been described by Lee, Skjelbreia, and Raichlen (1982); and a description of the cnoidal waves and their kinematics generated with the tank horizontal has been given by Raichlen and Lee (1984). As mentioned earlier, to produce breaking waves the wave tank was tilted and both solitary and cnoidal waves wave breaking could be induced at pre-determined locations by modifying the characteristics of the wave plate trajectory, i.e., the relative wave height at the point of generation: (H_0/h_0) , where H is the wave height, h is the depth, and the subscript $_0$ indicates the location is at the wave generator.

It was found by Skjelbreia (1987) that just prior to and at wave breaking, wire resistance wave gages normally used to define the free surface were inaccurate when the free surface changed rapidly with time. Problems using this type of gage increased after breaking when air is entrained. It was apparent that observations made using high speed motion picture techniques would eliminate such questions regarding the gage response and the effect of the variation of the electrical conductance of the air-water mixture. Therefore, the wave shape and wave heights were obtained from the frame-by-frame analysis of projected images of the wave obtained from high speed motion pictures. The 16 mm. camera which was used can operate at film speeds which can be continuously adjusted up

to a maximum of 500 frames per second with adjustable shutter speeds to 1/4000 sec. Timing marks every 1/100 sec. are automatically imaged on the film frames. The camera and the necessary lights were mounted to a carriage which could be moved along precision rails mounted to the walls of the tank. The carriage was moved manually so that the breaking region of the wave was approximately centered in each film frame. This was relatively easy even though the wave speed decreased as the wave approached the shoreline. There was probably an error of about ± 1 mm using this technique due to the meniscus which formed on the sidewall of the tank.

An estimate of the size of the roller on the front face of the breaker was made also using the individual frames of the high speed motion pictures. The cross sectional area of the *bubble mass* was used as a measure of the roller size, and its cross section area was estimated from the projection of the *bubble mass* on the sidewall of the tank as seen in the individual film frames. Only the *bubble mass* seen on the front face of the wave was used for this definition; bubbles appearing further back in the wave were not included in this defined area. Several aspects of this measurement will be discussed more fully later.

RESULTS AND DISCUSSION OF RESULTS

It is instructive, before discussing the more quantitative aspects of wave breaking obtained from the experiments conducted, to view certain features of breaking in a qualitative sense. This can be done from sequences of frames of selected high speed motion pictures taken in the course of the experiments.

A series of frames taken from a 300 frame per second high speed movie of a breaking solitary wave are presented in Figure 1. The solitary wave was generated in the wave tank which was sloped at 0.0191 m/m with a water depth at the wave generator of 43.25 cm; the experiment is denoted as Experiment P-1. In each frame the bottom of the tank can be seen along with the vertical members which support the glass sidewalls. The numbers in each frame indicate distance in meters measured from one end of the tank, and the horizontal bars superposed on the short vertical ones define the still water level for the experiments. (The lowest line corresponds to the still water level for this group of experiments.) The distance between crosses is 50 cm.; for convenience a bar-scale is shown at the bottom of the figure. For reference, the mean position of the wave machine is at Station 37.71 m.

In Figure 1 the sequence of breaking for a plunging breaker can be followed from the position just at breaking (shown in the upper lefthand frame at tank station 22.12 m.) to the post breaking position (shown in the lower righthand frame). Breaking is defined as occurring when the face of the wave in the crest region becomes vertical shortly before overturning takes place. This definition was used for both plunging and spilling breakers. The depth at breaking is: $h_b = 13.50$ cm. and the wave height at breaking is: $H_b = 16.50$ cm as obtained directly from the frame. As one views the sequence of frames, the overturning of the crest and the subsequent formation of the jet just after breaking can be seen as the wave crest approaches $x = 22$ m. The wave propagates shoreward about one breaking depth before the jet impinges with splashup on the front face of the wave. (See the third frame in the center row of photographs.) At that point the wave begins to collapse and change shape while generating the roller on the front face of the wave. The process of the "folding" of the air into the wave can be seen easily. As the wave propagates shoreward it appears to travel through the *bubble mass* as can be seen in the last few photographs of the sequence. The vortical motion so generated can be seen easily. It should be noted that the total distance the wave has travelled in the complete sequence of photographs shown is only about 1.5 m. or about 12 breaking depths.

A qualitative comparison between a breaking solitary wave and a breaking cnoidal wave can be made by reviewing the series of photographs presented in Figure 2. The left-hand column of frames is for the plunging breaking solitary wave which was shown in Figure 1 (Experiment P-1) with the relative distance shoreward of breaking indicated beneath each frame. The right-hand column corresponds to a plunging breaking cnoidal wave (Experiment ACN-4) with the relative shoreward distance from breaking also shown

below each frame. In all cases where the results for the cnoidal waves are shown, the photographs and data are for the fourth wave in the wave train. This wave was used as it is far enough back in the wave train so that it appears fully developed and yet not so far back that it would be affected by the reflections from the wave generator of waves which are reflected from the slope. In both cases the flume slope was 0.0191 m/m which is the steepest the wave tank can be tilted. Again the crosses are spaced 50 cm. apart and are located at the still water level; a bar-scale is shown for each sequence of photographs. The cnoidal wave has an Ursell Number at the point of generation which is about 278. (The Ursell Number at the wave generator is defined as: $(HL^2/h^3)_0$, where H is the wave height, h is the water depth, L is the computed wave length.) With that in mind, it is seen, perhaps as would be expected, there are striking similarities between these two types of breaking waves. The solitary wave shows the classic profile of a plunging wave whereas the cnoidal wave shown just to the right, for the locations chosen, shows the jet as it is being ejected from the crest. The shape of the jet appears to be more complex than that for the solitary wave. Certain of the differences observed between the solitary and the cnoidal waves are probably due, for the cnoidal case, to the influence of the prior breaking waves. As waves break they leave behind a turbulent field which, along with the effect of the offshore current generated by the runup and rundown of the waves at the shoreline, must influence the breaking of subsequent waves in the train. Nevertheless, after breaking occurs, the shape of the waves as they propagate shoreward are similar for the two cases. This suggests that the post breaking region is strongly controlled by the details of the flow at the crest during the overturning process. This is probably reasonably similar for the cases shown indicating that the details of the initial wave, i.e., solitary or cnoidal, probably are not too important in this regard.

In Figures 3 and 4, photographs are presented showing the breaking of cnoidal waves with Ursell Numbers, at generation, of 278 and 98.3, respectively, with the wave tank sloped at 0.0191 m/m. In a general way the photographs are similar for both the breaking and post breaking regions. The irregularities near the crest in the second photograph on the left in Figure 3 may be an indication of a wave propagating offshore generated at the shoreline by the runup-rundown process. Further into the sequence it is seen that the broken wave travels through the vortices generated during the breaking process, e.g., see the last photographs of the two sequences. The depth to which the bubbles generated at the water surface during the breaking process penetrate when the wave is greater than ten breaking depths shoreward of the breaking location is somewhat surprising in these figures, as well as in Figure 1 for the solitary wave. (Similar effects have been observed by Nadaoka (1986).) A series of photographs is presented in Figure 4 for the cnoidal wave with an Ursell Number of 98.3 when breaking in the tank with a bottom slope of 0.0191 m/m. There is little difference in the overall features seen in the photographs for similar distances shoreward of breaking for the waves shown in Figures 3 and 4 suggesting that the processes among the three waves: the solitary wave and the two cnoidal waves for the same bottom slope are similar.

The variation of the relative wave height at breaking, $(H/h)_b$, with the bottom slope, S , for the solitary waves and the cnoidal waves which were tested is presented in Figure 5. Plotted next to each data point is the relative wave height at generation: H_0/h_0 . In this figure the nondimensional parameter: $T(g/h_0)^{1/2}$ is used to define the two different cnoidal waves which were used; Table 1 shows the experimental conditions for these cnoidal waves. The slopes were chosen to generate a range of breaking waves from spilling to plunging. The spilling wave occurs at a slope of 0.0061 m/m with a gradual change to plunging at a slope of 0.0191 m/m. This figure demonstrates that the differences between spilling and plunging breakers are not distinct; perhaps they are more related to the *intensity* of the overturning jet associated with breaking rather than major differences in the waves themselves. The interested reader is directed to Papanicolaou and Raichlen (1987) for a discussion of certain of these aspects for the solitary wave.

In Figure 5 self-similarity at breaking for the solitary wave is demonstrated by the three data points shown for a tank slope of 0.0126 m/m. For that case the relative breaking height is essentially the same, independent of the generation conditions. The

water depth at the location of the wave generator was the same for the three different experiments, hence, the waves break at different locations. An experimental curve is shown for the solitary wave which, if extrapolated, tends to a value of relative height at breaking of about 0.8 for a horizontal bed. The data for the cnoidal waves vary in a similar manner with slope as the corresponding data for the solitary waves. Thus, there appears to be a strong similarity in the trends of relative breaking height with increasing slope for solitary and cnoidal breaking waves. The differences observed between the relative breaking heights of solitary and cnoidal waves for the same slopes are probably related to the influence of the prior breaking waves on the observed wave in the train, i.e., the fourth wave.

Table 1 Experimental Conditions for Cnoidal Waves

In Figure 6 the variation of the breaking wave heights for the cnoidal waves is shown (normalized by the breaking solitary wave height) as a function of the generation Ursell Number for each of two different wave tank slopes. It is interesting to see that the effect of slope does not appear significant for these data even though at the smaller slope the breaking wave is essentially a spilling wave and at the larger slope it is a plunging wave (see Figures 3 and 4).

The variation of the relative wave height, H/H_b , with distance shoreward of breaking, $\Delta x = (x - x_b)$, is presented in a nondimensional manner in Figures 7 and 8 for waves breaking on a slope of 0.0191 m/m and 0.0061 m/m, respectively. (The location of the point of observation is denoted as x and the location of the breaking position is x_b .) For each tank slope, data are shown for solitary and cnoidal waves with different non-dimensional generation times. It should be mentioned, after breaking the wave height defined corresponds to the height for the portion of the wave which appears to have little air entrained. If, for example, one refers to the last frame presented in Figure 4, it is seen that the height of the roller (or *bubble mass*) is somewhat greater than that corresponding to the clearer region behind; the height used in Figure 7 corresponds to the latter. As seen in Figures 7 and 8, and also best shown in the photographs presented in Figure 2, both the cnoidal and the solitary waves propagate some distance shoreward of breaking with little effect on the wave height. This is in accord with the observations of Galvin (1968), (1969); the Shore Protection Manual of the U.S. Army Corps of Engineers (1984) follows these observations and recommends that the post-breaking distance during which the wave height changes only slightly be defined as: $(\Delta x/h_b) = (4 - 9.25S)(H/h)_b$. For the solitary wave of Figure 7 the distance computed from this expression is about 4.7.

Figure 7 shows that, for the solitary wave, at a location of about five breaking depths the rate of change of the wave height with distance begins to increase. For the two cnoidal waves, i.e., $U = 98.3$ and 278, there is a more rapid decrease in relative wave height with distance shoreward of $\Delta x/h_b = 3$ than for the solitary wave. This is probably due to the influence of the preceding waves on the breaking process. This can be seen easily in Table 2 where the exponent, n , in the expression: $(H/H_b) \sim (\Delta x/h_b)^n$ is presented for the various experiments for $4 < \Delta x/h_b < 8$. Thus, these data indicate an increase in the energy dissipation in the post breaking region of periodic waves compared to solitary waves. The data shown in Figure 7 for the region of $7 < \Delta x/h_b < 15$ shows a relatively constant relative wave height of about $H/H_b = 0.5$. This is the beginning of the region where a bore is formed and the wave height changes more slowly. Horikawa and Kuo (1966) show, in this bore region, that the wave height relative to the local water depth

Horikawa and Kuo (1966) for periodic waves breaking on a slope of 0.0154 for the region of data from these experiments. (Similar data have been presented by Svendsen et al (1978) for periodic waves breaking on a slope of 0.0292.)

In Figure 8 the variation of relative wave height with distance is presented for a solitary wave and for two cnoidal waves with Ursell Numbers of about 700 and 260 breaking on a bottom slope of 0.0061 m/m. Instead of the plunging waves in Figure 7, the waves break as spilling breakers. The first observation is that for $\Delta x/h_b \geq 3$ the rate of decrease in the relative wave height is less for the spilling breaker than it is for the plunging breaker. This has been shown, with reference to the exponent, n , in Table 2. In fact, for the spilling breaker the relative change in wave height with distance shoreward of breaking is *similar* for the solitary and two cnoidal waves shown; actually the rates are somewhat less for the cnoidal waves as compared to the solitary wave. For the spilling waves the relative wave height becomes approximately constant at about $H/H_b = 0.5$ to 0.6 for: $15 \leq \Delta x/h_b \leq 25$ which, similar to the plunging wave case, is where the broken waves become bores and propagate shoreward with a smaller change in relative height. The consistency of the data acquisition and analysis is shown by the agreement of the data for Experiments ACN 7-1 and ACN 7-2 conducted at separate times with the same experimental conditions. It is interesting to observe that the rate of change of relative wave height with distance for the spilling and plunging solitary waves shown in Figures 7 and 8 are similar.

It was realized from reviewing the motion pictures that the change in wave height in the initial region after breaking was related also to the change in the wave shape in addition to the effects of energy dissipation. However, the effects of energy dissipation must not be too great in the region just after breaking, since in that region the overturning crest associated with the breaking process has not had time to fully generate the vortical motion observed further shoreward of breaking. To explore this with the data available from the current experiments, an aspect ratio of the wave was used which was defined as the ratio of the wave height, H , to the width of the wave, W , measured one half of the distance from the still water level to the crest. The variation of H/W with relative distance from breaking, $\Delta x/h_b$, is presented in Figure 9 for plunging breaking solitary and cnoidal waves. (A definition sketch for the width, W , is shown in the inset.) For this slope, i.e., $S = 0.0191$ m/m, the Ursell Numbers for the two cnoidal waves are 98.3 and 278, respectively. In the region from breaking to about two breaking depths shoreward of breaking the aspect ratio is relatively constant and equal to between about 0.5 and 0.6 for both the solitary and the cnoidal waves. There is a relatively gradual decrease in H/W for the solitary wave when $2 \leq \Delta x/h_b \leq 5$; for $\Delta x/h_b > 5$ the aspect ratio decreases more rapidly. In the case of the two cnoidal waves similar changes take place. If the variation of the aspect ratio with distance for this rapidly changing region is expressed as: $(H/W) \sim (\Delta x/h_b)^n$; the exponent n for experiments: P1, ACN4, and ACN2 are - 1.285, - 1.43, and - 1.17, respectively. Within the errors involved in the definition of the aspect ratio, it appears that the decrease in the aspect ratio with distance in this rapidly changing region is

similar for each of the three different waves.

Svendsen (1984) and Duncan (1981) have given attention to the size of the roller generated during the breaking process. Measurements were reported by Duncan (1981) using a breaker which was generated by a towed hydrofoil. These results were used by Svendsen (1984) to estimate the percentage of energy dissipated from breaking through the region referred to by him as the transition region. However, the experiments reported by Duncan (1981) were essentially steady ones, i.e., the hydrofoil moved at a constant velocity, whereas the wave breaking process is highly unsteady.

As mentioned in the previous section, the variation in roller size was determined in this study as a function of distance from breaking using the high speed motion pictures taken with the camera following the wave. The roller area was defined using the projection on the side of the wave tank of the area of the *bubble mass* which travels on the front face of the breaker. Obviously this technique can only provide an estimate of the roller area, but if it is done consistently, a comparison of this area can be made among the different types of waves used in these experiments. Examples of these projected areas can be seen easily in the photographs presented in Figures 1 through 4. There is some lateral variation to the *bubble mass*, as can be seen in the frame corresponding to $\Delta x/h_b = 8.99$ in Figure 2, so the technique used yields simply an *estimate* of the roller size. This is a crude measurement of the roller area, but at the very least it provides one other way by which the breaking process of solitary and cnoidal waves can be compared.

In Figure 10 the variation of the cross section area of the *bubble mass* normalized by the square of the breaking wave height, A/H_b^2 , is presented as a function of the relative distance shoreward of breaking, $\Delta x/h_b$, for a plunging solitary wave and two cnoidal waves breaking in the wave tank sloped to 0.0191 m/m. It is seen that, for the cases shown, the maximum value of the relative area is close to unity. The average value of the normalized roller area reported by Duncan (1981) from his steady experiments was: $A/H_b^2 = 0.86$. The *bubble mass* area ratio reaches a maximum between about seven and ten breaking depths shoreward of breaking. (The interested reader is directed to Papanicolaou and Raichlen (1987) for more detailed information on *bubble mass* areas for solitary waves.) Referring back to Figure 7, for the cnoidal waves, the maximum appears to be reached *after* the wave height has decreased at its maximum rate to the observed *plateau* in height. As would be expected, the area of the bubble mass increases significantly over the distance that the height is changing the most, i.e., for: $3 < \Delta x/h_b < 8$ the relative roller area increases by a factor of ten. The data for the solitary waves and the cnoidal waves with Ursell Numbers of 98.3 and 278 are quite similar in trend and in the maximum relative bubble areas.

The growth of the roller, i.e., the *bubble mass*, for spilling breakers was investigated also, and the results are presented in Figure 11. With the wave tank sloped to 0.0061 m/m both the solitary wave and the two cnoidal waves broke as spilling breakers where the overturning at the crest was observable but certainly not as dramatic as for the waves breaking on the steeper slope. The data from two different experiments for the same conditions, i.e., $U = 700$, are in good agreement indicating that comparisons of *bubble mass* areas made among the different waves are reasonable. In comparing the relative roller area for the solitary wave to that observed for the cnoidal waves it was found that there was very little difference in the trend of the data. The relative areas grew from about 0.1 to a maximum for: $2 < \Delta x/h_b < 10$. However, unlike the plunging breakers, the maximum relative areas are somewhat different. They range from about 0.5 to 0.6 for the cnoidal waves to 0.8 for the solitary waves. Although this may be within the range of the accuracy of the data reduction, it is also possible (and reasonable) that the rate of growth of the roller is slower for the spilling breaker compared to the plunging breaker. Thus, assuming this area is related to the associated energy dissipation, Figures 10 and 11 support the generally held hypothesis that the energy dissipation for spilling breakers is less than that for plunging breakers. This also agrees with the observations made in comparing Figures 7 and 8 for the change in relative wave height after breaking.

Figure 10 Variation of Relative Bubble Mass after Breaking with Relative Distance ($S = 0.0191 \text{ m/m}$).

Figure 11 Variation of Relative Bubble Mass after Breaking with Relative Distance ($S = 0.0061 \text{ m/m}$).

Conclusions

The following major conclusions may be drawn from this study:

1. The data for breaking solitary and cnoidal waves each show plunging waves differ from spilling waves primarily in the *rate* of change of the properties investigated, not in overall characteristics.
2. The relative breaking height $(H/h)_b$, for the solitary and cnoidal waves tested, increases with slope and for a given slope the relative breaking wave height is a maximum for solitary waves compared to the cnoidal waves.
3. The breaking of a solitary wave which is between a spilling and a plunging breaker is self-similar.
4. There is a region of three to five depths shoreward from breaking where the wave height is relatively unchanged, followed by a region of three to five breaking depths over which major changes in wave height and shape take place. It was apparent from the data that the changes in height for the cnoidal waves with distance after breaking was significantly greater for the plunging waves compared to the spilling waves. The comparable changes for the solitary waves (plunging and spilling) were similar.
5. The aspect ratio of the wave, H/W , changes in a manner similar to the height. For the plunging case, for which this was defined, the decrease of the aspect ratio in the rapidly changing region was similar for the solitary and the two cnoidal waves.
6. The *bubble mass* on the front face of the wave grows from zero, reaches a maximum, and decreases; the maximum relative size of the mass expressed as A/H_b^2 is of the order of unity.
7. Solitary and cnoidal waves exhibit reasonably similar changes in wave height and *bubble mass* for each type of breaking wave investigated (spilling or plunging) indicating that effects on the waves of breaking for these translatory and oscillatory waves may be similar.

CHAPTER 27

Numerical Modeling of Wave Deformation with a Current

Susumu OHNAKA*, Akira WATANABE** and Masahiko ISOBE***

ABSTRACT

A numerical computation method for a wave field coexisting with a current is presented to study wave-current interaction on a slowly varying bottom topography. Derivation is given for a new set of time-dependent mild-slope equations extended to a wave and current coexisting field, which can deal with wave deformation due to combined refraction, diffraction, reflection and breaking as well as to wave-current interaction. Discussion is made on the numerical computation schemes, boundary conditions and breaking conditions. Some examples of the numerical computations are shown for wave and current coexisting fields.

1. INTRODUCTION

Many efforts have been devoted to the evaluation of wave deformation in the shallow water region with numerical models. The mild-slope equation has been presented and used by Berkhoff (1972) to study combined wave refraction and diffraction on a slowly varying bottom topography. Watanabe and Maruyama (1986) have proposed a time-dependent version of the mild-slope equation, which can be more easily solved numerically and can deal with not only the combined refraction, diffraction and reflection but also wave breaking and decay in the surf zone.

In these equations, however, wave-current interaction is ignored. Coastal and nearshore currents such as rip current, longshore current and river discharge flow affect the wave deformation and therefore it is important to estimate the wave-current interaction in order to accurately predict the nearshore waves and currents and the resultant sediment transport.

For a wave field coexisting with a varying current, three kinds of wave equations and models have been proposed by Booij (1981), Liu (1983) and Kirby (1984), respectively. All these three models employ elliptic-type differential equations which are in general difficult to numerically solve. Hence these models are often approximated by parabolic equations, and then they are not applicable to the wave field including significant reflection due to structures.

In the present study, a new set of the time-dependent mild-slope equations extended to a wave and current coexisting field is derived and the numerical computation method is discussed. Some results of the computation are compared with analytical solutions and experimental results. The model is also applied to computing waves and currents under practical conditions including the presence of structures with consideration of the wave-current interaction.

2. DERIVATION OF GOVERNING EQUATIONS

The mild-slope equation presented by Berkhoff (1972) is the second-order partial differential equation. On the other hand, the time-dependent mild-slope equations proposed by Watanabe and Maruyama (1986) consist of two first-order equations, which are obtained by separating the original mild-slope equation in terms of the water surface elevation and the flow rate. They also include a term for the energy dissipation due to breaking. The numerical computation is conducted for every time-step, and it is easy to deal with boundary conditions in general and to calculate local wave direction needed for introducing partially reflective boundaries and for solving the dispersion relation in a wave and current coexisting field.

As mentioned before, three kinds of elliptic equations have been proposed for a wave and current coexisting field. Among them, the equation proposed by Kirby (1984), which exactly satisfies the conservation equation of wave action, is given by

$$\frac{D^2\phi}{Dt^2} + (\nabla \cdot U) \frac{D\phi}{Dt} - \nabla \cdot (C \cdot C_g \nabla \phi) + (\sigma^2 - k^2 C \cdot C_g) \phi = 0 \quad (1)$$

where $D/Dt = \partial/\partial t + U \cdot \nabla$, ∇ is the horizontal gradient operator, ϕ the complex velocity potential at the mean water level, U the steady current velocity vector, σ the intrinsic angular frequency, k the wave number vector, and C and C_g the phase and group velocity vectors calculated with σ , which is determined from

$$\omega = \sigma + k \cdot U, \quad \sigma^2 = gk \tanh kh \quad (2)$$

where ω is the apparent angular frequency, h the water depth, and g the acceleration due to gravity. The velocity potential at an elevation z will be given by

$$\Phi(x, z, t) = \phi(x, t) f(z) \tag{3}$$

where $f(z)$ is the vertical distribution function represented by

$$f(z) = \cosh k(h+z) / \cosh kh \tag{4}$$

Now we separate Eq. (1) into two equations expressed in terms of the surface elevation ζ and the flow rate vector Q instead of ϕ . The flow rate vector Q is defined by

$$Q = \int_{-h}^0 \nabla \phi \, dz \tag{5}$$

Substituting Eqs. (3) and (4) into Eq. (5), we obtain

$$Q = C^2 \nabla \phi / g \tag{6}$$

On the other hand, the kinematic boundary condition at the water surface including the convection term due to a steady current requires

$$\zeta = - (1/g) D\phi / Dt \tag{7}$$

Here the complex velocity potential ϕ is expressed in terms of the amplitude and the phase as

$$\phi = \phi(x) e^{i\psi} \tag{8}$$

where $\psi = k \cdot x - \omega t$ is the phase function. When we ignore change in the amplitude of the velocity potential as compared with change in the phase, $D\phi / Dt$ is represented as

$$D\phi / Dt = -i\sigma\phi \tag{9}$$

Substitution of Eq. (9) into Eq. (7) yields the following expression of the surface elevation ζ in terms of ϕ :

$$\zeta = i(\sigma/g) \phi \tag{10}$$

Substituting Eq. (10) into Eq. (5) and differentiating with t , we obtain

$$\partial Q / \partial t + \omega C^2 \nabla(\zeta / \sigma) = 0 \tag{11}$$

On the other hand, using Eqs. (7) and (9), ϕ is expressed as

$$\phi = (g / \sigma \omega) \partial \zeta / \partial t \tag{12}$$

Substituting Eqs. (6), (7) and (12) into Eq. (1), we obtain

$$m \partial \zeta / \partial t + \nabla \cdot (U \zeta) + \nabla \cdot (n Q) = 0, \tag{13}$$

$$m = 1 + (\sigma / \omega) (n - 1), \quad n = C_g / C$$

Equations (11) and (13) are time-dependent mild-slope equations extended to a wave and current coexisting field. If we set the steady current

velocity vector $U = 0$, these equations reduce to the ones proposed by Watanabe and Maruyama (1986), though the latter include an additional term for the energy dissipation due to breaking.

3. NUMERICAL COMPUTATION METHOD

Equations (11) and (13) are solved by using a finite difference method. A study area is divided into grid cells and a staggered mesh scheme is employed as shown in Fig. 1. Successive computation is conducted alternately for the flow rate Q and for the water surface elevation ζ . If the convection term due to the steady current in Eq. (13) is neglected, Eqs. (11) and (13) can be easily solved by using an explicit finite difference scheme. However, when this terms is included as needed for general wave and current coexisting systems, some problems appear in numerical computations, such as numerical diffusion and unphysical reflection from the boundaries. In order to determine the most appropriate one among various finite difference schemes, we consider a one-dimensional wave and current field. The following notation is used.

$$\zeta_i^j = \zeta(i\Delta x, j\Delta t) \tag{14}$$

$$Q_i^j = Q\{(i+1/2)\Delta x, (j+1/2)\Delta t\} \tag{15}$$

namely the subscript i denotes the spatial point and the superscript j denotes the time-step. Equations (11) and (13) for the one-dimensional case are discretized to yield

$$m_i \frac{\zeta_i^{j+1} - \zeta_i^j}{\Delta t} + \frac{\delta(U\zeta)}{\delta x} + \frac{n_i Q_i^j - n_{i-1} Q_{i-1}^j}{\Delta x} = 0 \tag{16}$$

$$\frac{Q_i^{j+1} - Q_i^j}{\Delta t} + \omega C_i^2 \frac{(\zeta/o)_{i+1}^j - (\zeta/o)_i^j}{\Delta x} = 0 \tag{17}$$

where $m_i = 1 + (\sigma_i / \omega) (n_i - 1)$. In Eq. (17), the flow rate Q_i^{j+1} can be calculated explicitly since the surface elevations ζ_{i+1}^j and ζ_i^j are known values. The problem is how to discretize the convection term $\delta(U\zeta) / \delta x$ in Eq. (16).

First we use two types of the modified Euler method, which is of an implicit scheme. Type I in Table 1 is an up-wind difference scheme. With this scheme, however, a numerical diffusion term shown in Table 1 is added to Eq. (16). Such a diffusion term doesn't appear when a central difference scheme (Type II) is used. Types I and II are of implicit type, and therefore it will be hard to extend them to computations of two-dimensional wave fields.

Next we discuss explicit difference scheme. Type III is an up-wind difference scheme and Type IV is a central difference scheme. With either of these schemes, however, a numerical diffusion term is added to Eq. (16) as shown in Table 1. This problem is solved by adopting the Alternating Direction Explicit (A. D. E.) method as presented as Type V in Table 1. In this scheme a value at a point $(i-1)$ at a time-step (j) is replaced with the value calculated at the time-step $(j+1)$ just before. By using this method, Eq. (16) can be solved explicitly without numerical diffusion.

Now the treatment of nonreflective boundary condition is discussed. For the equations proposed by Watanabe and Maruyama (1986), which include no convection term due to currents, the nonreflective boundary condition is given by the flow rate. Namely the flow rate at a point x on

the boundary at time t , Q_x^t , is calculated by the flow rate at the inner point $x - \Delta x$ at time $t - \tau$, $Q_{x-\Delta x}^{t-\tau}$. If this boundary condition given by the

flow rate is used in the calculation for a wave and current coexisting field, the surface elevation at the point $x + \Delta x/2$ is needed in order to evaluate the convection term in Eq. (16) with the scheme of Type V. This point is, however, located outside the calculation region, and therefore we must give the convection term along the boundary by backward difference scheme. Using this scheme, the second term in Eq. (16) is evaluated at the point $x - \Delta x/2$, whereas the third term is evaluated at the point x . The difference of the evaluation points causes unphysical reflection from the boundary.

In order to evaluate these terms at the same point, the calculation region is extended up to the point $x + \Delta x/2$ and the boundary condition is given by the surface elevation ζ instead of the flow rate Q , as shown in Fig. 2. The surface elevation at the point $x + \Delta x/2$ on the boundary at time t is given by the one at the inner point $x - \Delta x/2$, at the time $t - \tau$, using a characteristic line $C + U$, as :

$$\zeta_{x+\Delta x/2}^t = \zeta_{x-\Delta x/2}^{t-\tau} \tag{18}$$

where τ is defined by

$$\tau = \Delta x / (C + U) \tag{19}$$

By using this boundary condition, the surface elevation at the point $x + \Delta x/2$ on the boundary is given independently of the difference scheme. Surface elevations at inner points are given by A. D. E. difference scheme, which can evaluate the second and third terms in Eq. (16) at the same point, and consequently we can avoid unphysical reflection.

For the two-dimensional case, τ is calculated from the next equation instead of Eq. (19).

$$\tau = \Delta x \cos a_n / (C + U) \tag{20}$$

where a_n is the direction angle of the incident wave component measured from the normal line to the boundary.

By applying this procedure to a nonreflective boundary, the offshore open boundary condition is set in terms of the surface elevation as

Fig. 2 Nonreflective boundary condition.

$$\zeta^t(x_0, y_0) = a_i \sin(kx_0 + ky_0 - \omega t) + \zeta_R^{t-\tau}(x_0 + \Delta x, y_0)$$

$$\zeta_R^{t-\tau}(x_0 + \Delta x, y_0) = \zeta^{t-\tau}(x_0 + \Delta x, y_0) - a_i \sin\{k(x_0 + \Delta x) + ky_0 - \omega t\}$$
(21)

where a_i is the incident wave amplitude.

4. RESULTS OF NUMERICAL COMPUTATION

To examine the applicability of these equations and method, numerical computations have been performed for two cases of wave deformation due to a current only.

The first case is a one-dimensional wave and current field as shown in Fig. 3. Figure 4 shows the wave height change in the shoreward direction in the steady state. In this figure H is the wave height, C the wave celerity and subscript o denotes quantities at the location where no current exists. The wave heights change corresponding to the current intensity and direction. Waves freely pass through the nonreflective boundary, and no unphysical reflection appears.

Figure 5 shows time histories of the surface elevation at the boundary. The wave amplitudes and the arrival time to the boundary change according to the difference of currents.

The numerical computation results are compared with the analytical solutions in Fig. 6. Solid lines show the analytical solutions given by the wave action conservation equation, and solid circles show the numerical solutions. The numerical solutions agree quite well with the analytical solutions. On the other hand, if we neglect the scalar product $k \cdot U$ in the dispersion relation, computations become easier particularly for a two-dimensional case. However if we set $\sigma = \omega$, both the numerical and analytical solutions deviate far from the true analytical solutions. From these results, it is confirmed that the scalar product $k \cdot U$ in the dispersion relation cannot be neglected for a wave and current coexisting system.

Fig. 3 Calculation condition for a one-dimensional wave and current field.

Fig. 4 Wave height change due to a current.

Fig. 5 Time history of the surface elevation at the boundary.

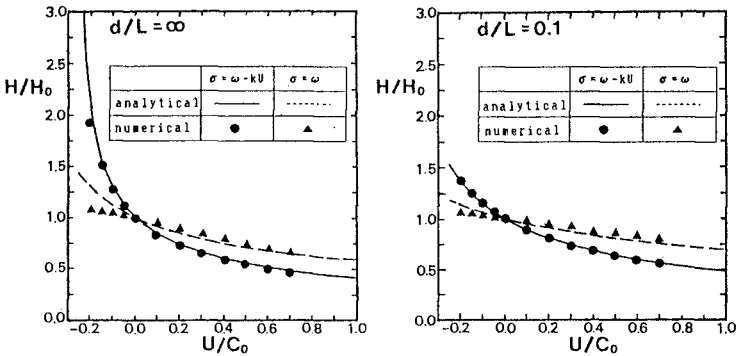

Fig. 6 Comparisons between numerical and analytical solutions of the wave height change due to a current.

The second case is for the wave refraction due to a current. The steady current is assumed to change in the x-direction only and waves are incident obliquely into the constant depth region as shown in Fig. 7. In this calculation, for the wave direction needed for solving the dispersion relation, the analytical solution given by Longuet-Higgins (1961) is adopted. The numerical solutions for the wave height and direction are compared with the analytical solutions in Fig. 8. Here the wave direction in the numerical calculation has been obtained from the principal direction of the flow rate vector. The numerical results agree well with the analytical solutions.

Fig. 7 Calculation condition for wave refraction due to a current.

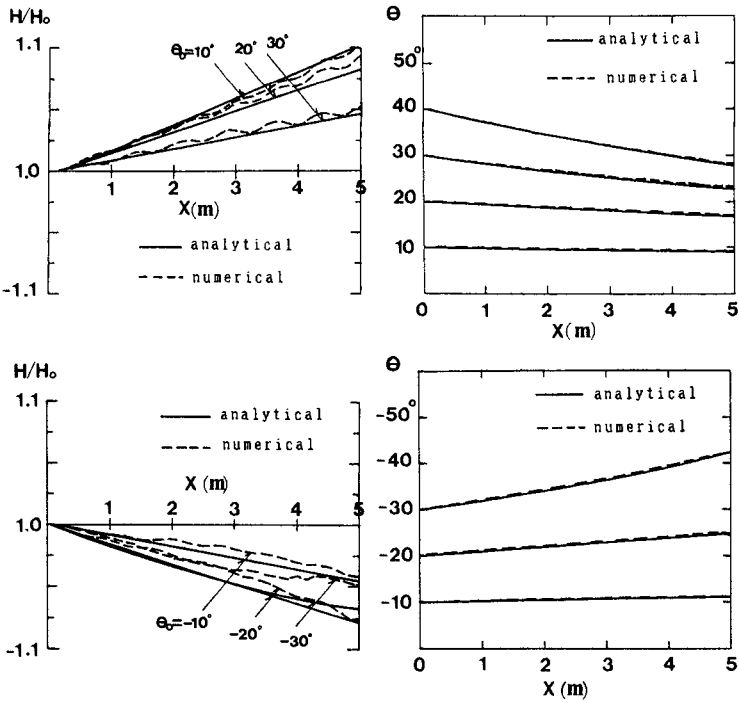

Fig. 8 Comparisons between numerical and analytical solutions of the wave height and direction.

5. DETERMINATION OF THE BREAKER LINE AND WAVES IN THE SURF ZONE

First we discuss the determination of the location of the breaker line which is very important to properly predict nearshore wave and current fields.

Goda (1970) has presented a breaker index diagram which is expressed in terms of the ratio of the depth at the breaking point h_b to the equivalent deepwater wave height H_0' as a function of the deepwater wave steepness H_0'/L_0 and the bottom slope s . This diagram can be used to evaluate the location of the breaking point of a single wave train. On the other hand, Watanabe *et al.* (1984) have proposed another breaker index diagram using the ratio of the amplitude of horizontal water particle velocity to the wave celerity at the breaking point, u_b / C_b , in order to extend to a composite wave field. This can be obtained from the Goda's breaker index diagram by converting the governing parameter from h_b / H_0' to u_b / C_b with a linear wave theory. It will be applicable even to a wave and current coexisting system when a moving coordinate relative to the current is adopted.

In order to examine the applicability of this breaker index, a series of laboratory experiments have been carried out on the breaking of waves on a current with the same or the adverse direction. Using the breaking depth h_b obtained from the experimental results, the horizontal water particle velocity amplitude u_b at the mean water level and the wave celerity C_b are calculated with a linear wave theory as

$$u_b = (H_b / 2) \sigma \cosh kh_b / \sinh kh_b \quad (22)$$

$$C_b = \sigma / k \quad (23)$$

where the wave number k and the angular frequency σ are calculated from the dispersion relation for a wave and current coexisting system as the values relative to the current. The breaker height H_b is calculated from the incident wave height H_i considering the bottom and side wall friction as

$$E_i(C_i + U_i) / \sigma_i = E_b(C_b + U_b) / \sigma_b - \Delta E / \omega \quad (24)$$

$$E = (1/8) \rho g H^2$$

where U is the mean velocity of the current, subscripts i and b denote quantities at the locations where the incident wave height and the breaking point are respectively given, and ΔE denotes the energy dissipation rate due to the bottom and side wall friction, which is calculated with the friction law from a wave and current coexisting system presented by Tanaka and Shuto (1981).

Using Eqs. (22) and (23), the ratio of the horizontal water particle

Fig. 9 Comparisons between the breaker index and experimental results for wave and current coexisting fields.

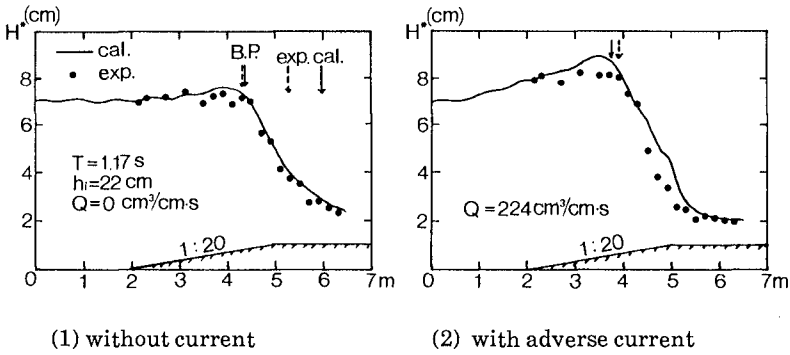

Fig. 10 Cross-shore distributions of the wave height.

Fig. 11 Cross-shore distributions of the mean water level.

velocity to the wave celerity, u_b / C_b , is calculated. The relation between this ratio and the relative water depth at the breaking point, h_b / L_b , is compared with the breaker index proposed by Watanabe *et al.* (1984) in Fig. 9, where the bottom slope s is 1/20 and 1/30, respectively. Different symbols are used for the experimental results according to the ratio of the steady current velocity at the breaking point to the wave celerity at the deepwater. For the cases of a strong adverse direction current, the experimental results show larger values of u_b / C_b than the breaker index. This will be attributed to the acceleration of breaking, which is ignored in Eq. (24), due to the turbulence transported toward the offshore by the current. As a whole, the experimental results agree fairly well with the breaker index. Hence this breaker index is applicable with a sufficient accuracy to a wave and current coexisting field.

Using the time-dependent mild-slope equations proposed in this study together with the above breaker index, numerical computations have been conducted for the location of the breaking point and the deformation of waves coexisting with a current on a uniformly sloping beach. For the computation of wave decay in the surf zone, the dissipation term proposed by Watanabe *et al.* (1988) has been added to Eq. (11).

Figure 10 shows the comparisons of the computed and the experimental result of the wave height distributions. The left figure is for a case of no current, while the right figure is for an adverse current with the flow rate of 224 cm³/cm/s. The experimental values are represented by the wave heights calculated from the root mean square of the measured surface elevation as $H^* = 2 \sqrt{2} \eta_{rms}$. The computed and the measured locations of the breaking point (B.P.) shows a good agreement regardless of the presence of currents. The wave height distributions also show a good overall agreement between the computations and the model. A slight overestimation of the wave height for the case of an adverse current is caused owing to the ignorance of the turbulence transported into the offshore across the breaking point by the current.

The comparisons of the mean water level between the computations and the measurements are shown in Fig. 11. The computed values agree well with the experimental results.

6. EXAMPLES OF THE NUMERICAL COMPUTATION FOR A PLANAR TWO-DIMENSIONAL CASE

The present numerical model has been applied to computing a wave field around detached breakwaters on a sloping beach. The detached breakwaters are placed at a water depth of 3 m and the bottom slope is 1/20. Waves are incident normal to the detached breakwaters and the contour lines, and the incident wave height and period are 3.0 m and 5.7 s.

In this computation including wave decay due to breaking, the wave height should become 0 along the shoreline, and therefore the shoreline boundary condition is set as

(1) without wave current interaction (2) with wave current interaction

Fig. 13 Distributions of the wave direction.

Fig. 14 Distributions of nearshore currents.

$$\zeta'(x_0, y_0) = 0 \quad (25)$$

Along the side boundaries, perfect reflection of waves and no-slip of mean currents are assumed.

Figure 12 shows distributions of the wave height with and without wave-current interaction: the figure on the left hand-side is the result without wave-current that with wave-current interaction. The change of the wave height can be observed when wave-current interaction is taken into consideration.

Distributions of the wave direction for both cases are shown in Fig. 13. Refraction due to the nearshore current is well observed near the shoreline.

Figure 14 show distributions of the nearshore current for both cases. Reduction of current can be observed when wave-current interaction is included.

7. CONCLUSIONS

A new set of time-dependent mild-slope equations has been derived for a wave and current coexisting field, and numerical computational method has been presented. Validity of this model has been demonstrated by comparisons of numerical results with analytical and experimental results. Then it has

been found that the breaker index expressed by the ratio of the water particle velocity to the wave celerity is applicable to a wave and current coexisting system. Finally this model has been applied to general two-dimensional wave and current fields and it has been found that wave-current interaction plays an important role in nearshore waves and currents.

CHAPTER 28

THEORETICAL MODEL FOR NEARSHORE CIRCULATIONS

Mikio Sasaki * M. JSCE
Akira Ozaki ** M. JSCE
Hiroshi Saeki *** M. JSCE

Abstract

The dynamics of nearshore circulations is investigated using mass, momentum and energy conservation equations with bottom friction, lateral mixing and wave-current interaction. By means of introducing a perturbation expansion for the mean variables, the first-order solutions are found in the surf and offshore zones according to the boundary conditions at the coast.

It is found that: (1) The rip velocity attains a maximum value in the offshore region near the break point as Yr^* becomes larger. (2) The longshore velocities become higher in the surf zone and lower in the offshore region with increasing Yr^* . (3) The rip and longshore velocities in the surf zone become relatively smaller due to the effects of the bottom friction, and that the rip and longshore velocities in the surf zone become smaller due to the wave-current interaction.

1. INTRODUCTION

Nearshore currents play an important role in the transportation of sediments and sea water in nearshore areas, and so several theoretical studies with respect to nearshore circulations have been presented. However many researchers take only bottom friction into account to avoid the mathematical complexities resulting from the lateral mixing, then the results obtained theoretically suggests that the lateral mixing should be included in more detailed analysis. The turbulent viscosity as well as wave-current interaction is important in flow field of nearshore circulations. In order to consider nearshore circulations

*** Professor, Hokkaido University, Kita 8 Nishi 13,
Sapporo, Japan

at the actual condition, it is necessary to have more realistic model for the dynamics of rip current circulation. In present paper, theoretical model including the bottom friction, the wave-current interaction and the lateral mixing is proposed.

According to Ozaki, Sasaki and Usui(1977), an important parameter on the dynamics of rip currents caused by normally incident waves in the symmetrical cellular(Harris,1967) is the nondimensional rip spacing Yr^* , where $Yr^*=Yr/X_B$, Yr = the rip spacing, X_B =the width of the surf zone. When the value of Yr^* is small, rip current circulation is confined to a very small region near the shore, and as the value of Yr^* becomes larger, rip currents flow rapidly from the surf zone to a large region where extends several surf zone widths offshore, and the rip currents grow intenser and narrower. The wave number and wave energy density are affected by the currents like the free jet. The wave-current interaction in nearshore circulations is important for the dynamics of rip currents.

2. BASIC FORMULATION

The beach considered here is of linear plane shape alongshore and of uniform slope offshore; the water depth, h , in the absence of waves is given by $h=sx$, where x is a distance in offshore direction normal to the shore line and s is the bottom slope. The waves are normally incident and break at a uniform distance from the shoreline at $x=x_B$ the breaker line. The fluid motion of currents is steady. The motion of water is described by Eqs.(1) and (2) in terms of the mean surface elevation ζ and the vertically averaged horizontal velocity components u and v in offshore and longshore directions,

$$ud=-\partial F/\partial y \quad vd=\partial F/\partial x \quad d=h+\zeta \quad (1)$$

$$u_j \frac{\partial u_i}{\partial x_j} + \frac{1}{\rho d} \frac{\partial S_{ij}}{\partial x_j} + g \frac{\partial \zeta}{\partial x_i} + \frac{B_i}{\rho d} - \frac{1}{\rho} \frac{\partial}{\partial x_j} (T_{ij}) = 0 \quad (2)$$

where d =the total mean depth, F =the transport stream function, S_{ij} =the radiation stress, T_{ij} =the effective stress, including effects of non-uniform velocity distribution, B_i =the bottom shear stress, and ρ is the fluid density. The steady state conservation of wave energy equation is

$$\frac{\partial}{\partial x_j} [(u_j + C_j)E] + S_{ij} \frac{\partial u_i}{\partial x_j} = -D \quad (3)$$

where $C_j = -(gd)^{1/2} + u, v$ is the velocity of the waves, E =the wave energy density and D =an energy dissipation function.

The radiation stress S_{ij} , the bottom shear stress B_i and the lateral stress T_{ij} can be written as follows:

$$S_{xx} = \frac{3}{2}E \quad S_{yy} = \frac{1}{2}E \quad S_{xy} = S_{yx} = 0 \quad (4)$$

$$B_x = 2fu \quad B_y = fv \quad f = \rho C_f \bar{u} / \pi \quad (5)$$

$$\bar{u} = \frac{1}{2} \frac{H}{d} \sqrt{gd} (x \leq x_B), \frac{1}{2} \frac{H_B}{d_B} \sqrt{gd_B} (x \geq x_B)$$

$$\frac{1}{\rho} T_{ij} = \nu t \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) - \frac{2}{3} K \delta_{ij} \quad (6)$$

$$\nu t = \mu \frac{ET}{\rho d} (x \leq x_B), \quad \mu \frac{E_B T}{\rho d_B} (x > x_B)$$

where H = the wave height, H_B = the breaking wave height, d_B = the breaking depth, νt = the eddy viscosity, T = the wave period, $E_B = \rho g H_B^2 / 8$, μ = a coefficient (≈ 0.5) and K = the turbulent kinetic energy. We assume that K can be modelled as a function of the energy dissipation rate D/ρ using the breaking-waves approximation (Wind and Vreugdenhil (1986))

$$K = (D/\rho)^{2/3} \quad (7)$$

The dissipation term D plays an important role in the energy balance. We assume that

$$D = \sqrt{gd} u' u_w \quad |u'| \propto |u_w| \quad (8)$$

where u' and u_w are the turbulence and the wave orbital velocity. Then, using the shallow water long wave approximation, the energy dissipation D is given by

$$D = q \sqrt{gd} \frac{E}{d} \quad (9)$$

where q = the dissipation factor. In the absence of the currents q is found by substituting Eq. (9) into the surf zone energy equation:

$$q = \frac{5}{2} m \quad m = \partial d_0 / \partial x \quad d_0 = h + \zeta_0 \quad (10)$$

where ζ_0 represents the wave set-up in an equilibrium state.

Small perturbations are imposed on the steady state, and the variables are expressed as

$$\begin{aligned} E &= E_0(x) + \epsilon E_1(x, y) \\ \zeta &= \zeta_0(x) + \epsilon \zeta_1(x, y) \\ F &= \epsilon F_1(x, y) \end{aligned} \quad (11)$$

$$D = D_0(x) + \epsilon D_1(x, y)$$

where ϵ is a small ordering parameter.

3. FIRST-ORDER SOLUTIONS

The energy dissipation to the first order becomes, by using the relation shown in Eq.(9),

$$D_1 = q_1 \sqrt{gd} \frac{E_1}{d} \quad (12)$$

Then the dissipation factor q_1 can be written as

$$q_1 = \frac{5}{2} m \left(\frac{d}{d\beta} \right) \quad (x \leq x\beta) \quad , \quad \frac{5}{2} m \left(\frac{d\beta}{d} \right) \quad (x \geq x\beta) \quad (13)$$

where the first expression is modified partly from Eq.(10) due to the necessity of keeping the solution bounded at the shoreline, and the offshore expression corresponds to the expression in the surf zone.

In deriving Eqs.(12) and (13) we have assumed $\zeta_0 \ll d_0$. The radiation stress S_{ij} can be expressed as

$$S_{xx} = \frac{3}{2} (E_0 + \epsilon E_1) \quad S_{yy} = \frac{1}{2} (E_0 + \epsilon E_1) \quad (14)$$

Dimensionless variables are introduced as follows:

$$\begin{aligned} \xi &= \frac{d}{d\beta} = \frac{X}{X\beta} & X &= x + x\beta & d &= mX & \eta &= \frac{Y}{Yr} \\ \zeta_1^* &= \frac{\zeta_1}{d\beta} & E_0^* &= \frac{E_0}{E\beta} & E_1^* &= \frac{E_1}{E\beta} \\ F^* &= \frac{F}{(u_0 d\beta X\beta)} & u_0 &= \sqrt{gd\beta} & u^* &= \frac{u}{u_0} & v^* &= \frac{v}{v_0} \end{aligned} \quad (15)$$

Making nondimensional form of Eqs.(1)-(3) and then eliminating the nondimensional perturbation energy E_1^* from a equation obtained by taking the curl of Eq.(2), finally, we find that, for the nondimensional stream function F^* only,

$$L(F^*) = 0 \quad (16)$$

where the differential operator L is defined as

$$L = L_1 \left(\frac{\xi^{3/2}}{q^*} L_2 \right) - \frac{5}{2} \xi^2 L_2 - C_4 L_1 \left(\frac{L_3}{q^*} \right) \quad (17)$$

where

$$L_1 = \xi \frac{\partial}{\partial \xi} + \frac{1}{2}$$

$$\begin{aligned}
L_2 = & \left(\frac{\partial^2}{\partial \xi^2} - \frac{\partial^2}{\partial \eta^2} \right) \left(v^* \left(\frac{1}{\xi} \frac{\partial^2}{\partial \xi^2} - \frac{1}{\xi} \frac{\partial}{\partial \xi} - \frac{1}{\xi} \frac{\partial^2}{\partial \eta^2} \right) \right) \\
& + \frac{\partial}{\partial \xi} \left(2 v^* \left(2 \frac{1}{\xi} \frac{\partial}{\partial \xi} - \frac{1}{\xi^2} \right) \right) \frac{\partial^2}{\partial \eta^2} \\
& - C_5 \left(\frac{C^*}{\xi} \frac{\partial^2}{\partial \xi^2} + \frac{\partial}{\partial \xi} \left(\frac{C^*}{\xi} \right) \frac{\partial}{\partial \xi} + 2 \frac{C^*}{\xi} \frac{\partial^2}{\partial \eta^2} \right) \\
L_3 = & \left(2E^*_0 \frac{1}{\xi} \frac{\partial}{\partial \xi} - \frac{7}{2} E^*_0 \frac{1}{\xi^2} + 2 \frac{\partial E^*_0}{\partial \xi} \frac{1}{\xi} \right) \frac{\partial^2}{\partial \eta^2} \\
q^*_1 = & \xi^{1/2} \quad (\xi \leq 1), \quad \xi^{-3/2} \quad (\xi \geq 1) \\
E^*_0 = & \xi^2 \quad (\xi \leq 1), \quad \xi^{-1/2} \quad (\xi \geq 1) \\
C^* = & \xi^{-1/2} \quad (\xi \leq 1), \quad \xi^{-1} \quad (\xi \geq 1) \\
v^*_t = & \xi \quad (\xi \leq 1), \quad 1 \quad (\xi \geq 1) \\
C_4 = & (\mu T \sqrt{g/d_{13}})^{-1} \\
C_5 = & (4/\mu \pi \gamma^2) (C_f/m) (\ln T \sqrt{g/d_{13}})^{-1}
\end{aligned} \tag{18}$$

where C_4 and C_5 are the nondimensional parameter representing the relative importance of the interaction and the bottom friction, and γ is the ratio of the waveheight to the local mean depth in the surf zone.

Equation (16) is to be solved subject to the following boundary conditions:

$$u^* = v^* = F^* = 0 \quad \text{at} \quad \xi = 0 \tag{19}$$

$$u^* = v^* = F^* = 0 \quad \text{at} \quad \xi \rightarrow \infty \tag{20}$$

$$(u^*_i)_{in} = (u^*_i)_{off} \quad \text{at} \quad \xi = 1 \tag{21}$$

$$\left(\frac{\partial u^*_i}{\partial \xi} \right)_{in} = \left(\frac{\partial u^*_i}{\partial \xi} \right)_{off} \quad \text{at} \quad \xi = 1$$

We introduce a function given by

$$F^*(\xi, \eta) = \phi(\xi) \text{sink} \eta \tag{22}$$

where $k = 2\pi/Yr^*$, Yr^* is the nondimensional rip spacing. The solution in the surf zone to Eq.(16) is written as a series of power of :

$$\phi = \sum_{m=0}^{\infty} a_m \xi^{\rho + \frac{m}{2}} \quad (23)$$

The roots of the indicial equation are $\rho = 0, 2, 2, 5/2, 3$. The first, second and third roots are dropped through Eq.(19). Hence the solution bounded at the shoreline in the surf zone is found as

$$\phi^*(\xi) = A_{S1} X_1(\xi) + A_{S2} X_2(\xi) \quad (24)$$

where

$$X_1 = \sum_{m=0}^{\infty} a_m \xi^{\rho_1 + \frac{m}{2}} \quad (a_0 = 1, \rho_1 = 3)$$

$$X_2 = \sum_{m=0}^{\infty} \frac{\partial}{\partial \rho} (a_m \xi^{\rho + \frac{m}{2}}) \Big|_{\rho = \rho_2} \quad (a_0 = \rho - 5/2, \rho_2 = 5/2)$$

$$\sum_{i=0}^{10} f_i(\rho + \frac{m-i}{2}) a_{m-i} = 0$$

$$f_0(a) = a(a-2)^2(a-\frac{5}{2})(a-3)$$

$$f_1(a) = -C_5 a(a-2)(a-\frac{5}{2})$$

$$f_2(a) = -\frac{5}{2} a(a-2)^2(a-3)$$

$$f_3(a) = \frac{5}{2} C_5 a(a-\frac{5}{2}) \quad (25)$$

$$f_4(a) = -2k^2 \{ a(a-1)^2 + \frac{3}{4} a - \frac{1}{2} \}$$

$$f_5(a) = k^2 a \{ 2C_4(a + \frac{1}{4}) + 2C_5 \}$$

$$f_6(a) = \frac{5}{2} k^2 (2a^2 - 3a + 2)$$

$$f_7(a) = -5C_5 k^2$$

$$f_8(a) = k^4(a + \frac{3}{2}) \quad f_9(a) = 0 \quad f_{10}(a) = -\frac{5}{2} k^4$$

where A_{S1} and A_{S2} are constants of integration.

In the deep-water region, we can consider the case of water of infinite depth, i.e. $\xi = \infty$. Hence the operator L given by Eq.(17) is rewritten as

$$L = \xi^4 \left(\frac{\partial}{\partial \xi} \left(\frac{\partial^2}{\partial \xi^2} + \frac{\partial^2}{\partial \eta^2} \right) \right) \left(\frac{\partial^2}{\partial \xi^2} + \frac{\partial^2}{\partial \eta^2} \right) \quad (26)$$

Using the general solution of Eq.(26), the approximate solution to Eq.(16) in the offshore region is found according to the boundary condition Eq.(20) as

$$\phi(\xi) = A_{01} e^{-k\xi} + A_{02} \xi e^{-k\xi} \quad (27)$$

where A_{01} and A_{02} are a constants of integration.

The fluid motion of the currents must be continuous at the breaker line as shown in Eq.(21). However three constants of the four constants, A_{S1} , A_{S2} , A_{01} and A_{02} , are determined through the matching condition, then, we introduce normalized velocities as follows:

$$U^* = \frac{u^*(\xi, \eta)}{u_1^*} \quad V^* = \frac{v^*(\xi, \eta)}{u_1^*} \quad (28)$$

where

$$u_1^* = u^*(\xi, \eta) \Big|_{\xi=1, \eta=0} \quad (29)$$

4. DISCUSSION

The normalized rip and longshore velocities, U^* and V^* , are shown in Figure 1. The Figure 1(a) suggests that the rip velocity attains a maximum value in the offshore region near the break point as Yr^* becomes larger. This results are in good agreement with laboratory experiments of Ozaki et al(1977) and Sasaki(1985). Figure 1(b) shows that the longshore velocities become higher in the surf zone and lower in the offshore region with increasing Yr^* . It is also found that the derivative of the longshore velocity is continuous at the breaker line. The solutions in the surf and offshore regions, Eqs.(24) and (27), are adequate in each zone including the neighbourhood of the break point.

Figure 2 shows the normalized rip and longshore velocities in case of $Yr^*=4$ and $C_4=1$ with respect to $C_5=0$ and 2. C_5 denotes the ratio of the bottom friction term to the lateral mixing term, and it means the relative effects of the bottom friction. Then, as shown in Figure 2, the rip and longshore velocities in the surf zone become relatively smaller due to the effects of the bottom friction.

Figure 3 shows the profiles of the normalized rip and longshore velocities in case of $Yr^*=4$ and $C_5=1.0$ with respect to $C_4=0.5, 1.0$ and 2.0. As above mentioned, C_4 means the effects of energy coupling between currents waves. Then, the figure demonstrates that the rip and longshore velocities in the surf zone become smaller due to the wave-current interaction.

5. CONCLUSIONS

We have extended the theory of rip currents to include the bottom friction, the wave-current interaction and the lateral mixing. By means of introducing a perturbation expansion for the mean variables, the first-order solutions are found in the surf and offshore zones according to the boundary conditions at the coast. In present model the continuity at the breaker line in the derivative of the longshore velocity keeps for the first time. The several results in this investigation conform with results of observations reported by Ozaki et al(1977) and Sasaki(1985).

CHAPTER 29

THE MEASURED PROPERTIES OF IRREGULAR WAVE BREAKING AND WAVE HEIGHT CHANGE AFTER BREAKING ON THE SLOPE

by Akira Seyama* and Akira Kimura**

ABSTRACT

Wave height change of the zero-down-cross waves on uniform slopes were examined experimentally. The properties of shoaling, breaking and decay after breaking for a total of about 4,000 irregular waves of the Pierson-Moskowitz type on 4 different slopes (1/10, 1/20, 1/30 and 1/50) were investigated. The shoaling property of the zero-down-cross waves can be approximated by the linear wave theory. However, the properties of breaking and decay after breaking differ considerably from those for periodic waves. The wave height water depth ratio (H/d) at the breaking point for the zero-down-cross waves is about 30% smaller than that for periodic waves on average despite the slopes. Wave height decay after breaking also differs from that for periodic waves and can be classified into three regions, i.e. shoaling, plunging and bore regions. Experimental equations for the breaking condition and wave height change after breaking are proposed in the study. A new definition of water depth for the zero-crossing wave analysis which can reduce the fluctuation in the plotted data is also proposed.

1. INTRODUCTION

Several models for irregular wave propagation in a surf zone have already been proposed by researchers such as Collins(1970), Battjes(1972), Kuo and Kuo(1972) and Goda(1975a). However, these models attempt to build a theory combining the theoretical or experimental properties of periodic waves i.e. breaking condition, energy dissipation, wave set-up and -down, etc. There have been few models which apply only the properties of the zero-(down or up)-crossing waves to complete the theory. There is a group of researchers, on the other hand, who have studied about the dynamic properties of irregular waves determined by the wave by wave method. The present author(1977), Isobe et al.(1980) and Sawaragi et al. (1980), for example, have examined experimentally the breaking properties of zero-crossing waves and showed that the averaged breaking wave height water depth ratio for zero-crossing irregular waves is smaller than that for periodic wave. This study also attempts to investigate the dynamic properties of zero-crossing irregular waves, especially their shoaling, breaking and decay after breaking, and tries to establish experimental equations for these properties.

2. EXPERIMENTS

The wave tank used was a 29m long, 0.5m wide and 0.75m deep glass sided tank. At one end of this wave tank, a hydro-electric type irregular wave generator was set up (Kimura et al., 1987). At the other end, a uniform slope was installed. The slopes investigated were 1/10, 1/20, 1/30 and 1/50. The wave profile was measured by wave gauges installed with an equal interval on the slope, and also taken by two video cameras from the side of the wave tank. The data recorder and the video-cameras were synchronized using a clock unit. The spectra of the irregular waves were of the Pierson-Moskowitz type with different peak frequencies from $f_p=0.7\text{Hz}$ to 1.0 Hz . The experiments for breaking, shoaling and decay after breaking were carried out separately. Individual measurements were carried out for about 1 hour. The wave profiles recorded by the wave gauges were discretized and stored in floppy discs. The records taken by the video cameras were read off using a function of the super-impose unit in a micro-computer system and stored also in floppy discs. Throughout this study, wave height was determined by the zero-down-cross method for the wave profile in the time domain.

3. BREAKING

The picture taken by the video-camera and the coordinates were super-imposed on the CRT(Cathode-Ray-Tube) of the micro-computer. Reading the video-tape frame by frame the vertical line is drawn on the CRT at the breaking point of the wave which broke within the sights of the video-cameras. Moving the video-tape back and forth, the times when the wave profile crossed the still water level at the vertical line and the maximum and minimum water levels within the zero-down-cross intervals at this line were read off on the CRT. The wave height and period can be, therefore, determined as if there were a wave gauge just at the breaking point. For further investigations, the zero-up-cross wave definition method was also applied for the same wave. The definition of breaking applied in this study was that of Stokes' i.e. the instance when a water particle start to come out from its crest. Sometimes temporal white forms were observed around wave crests which were left behind the wave movement. Those were not considered to be breaking in this study.

Table-1 Experimental conditions

Case	Slope	f_p (Hz)	$H_{1/3}$ (cm)	$T_{1/3}$ (s)	Data Total
1	1/10	0.7,0.9	8.2,8.0	1.33,1.01	800
2	1/20	0.7,1.0	8.2,7.9	1.33,0.95	1010
3	1/30	0.8	7.5	1.11	1004
4	1/50	0.8	7.5	1.11	1007

Table-1 shows the slope, peak frequency, significant wave height and period, and total number of waves investigated. Figure 1 shows the energy spectra of the wave profiles measured at the horizontal part ($h=45\text{cm}$) of the wave tank ($f_p=0.7\text{Hz}$ and 0.9Hz ; $\tan\theta=1/10$). Since the saw shape pattern on the spectrum, which is inherent when reflected and incident waves are composed, is not prominent, the reflection coefficient of the slope may be negligibly small.

Fig.1 Power spectra

Figures 2 (a), (b), (c) and (d) show the relation between the relative wave height (H_b/h_b) and relative water depth (h_b/L_0) at the breaking point, in which H_b and h_b are wave height and water depth at the breaking point respectively and L_0 is the deep water wave length. The solid lines in individual figures show the breaking condition for the periodic waves (Goda,1970). The fluctuation of the plotted data in individual figure is considerably large, especially in figure (a). The major reason for the large fluctuations may exist in the insufficient definition of irregular wave properties in the analysis. Several researchers have investigated the effects of additional wave parameters. Herbers (1984), Sawaragi et al.(1980) and Isobe et al.(1980), for example, examined the effect of local wave profile or irregularity of the former and latter waves. The present authors also investigated these effects (some are very difficult in practical application), but no significant property which can reduce the fluctuation has been detected. Therefore, no more wave properties other than those determined by the ordinary zero-down-cross method are applied in this study except for the newly introduced definition for water depth.

3.1 A new definition of water depth

Figure 3 shows applications of the zero-down-cross method for two different waves. If the wave height H and period T for these two waves are the same, and if no additional property such as wave crest height, for example, is used, these waves are considered to be the same in the ordinary definition. In this study, to distinguish the difference between these waves without any additional properties to those used in Fig.2, water depth is determined as,

$$d = h + (a_c - a_t) / 2 \tag{1}$$

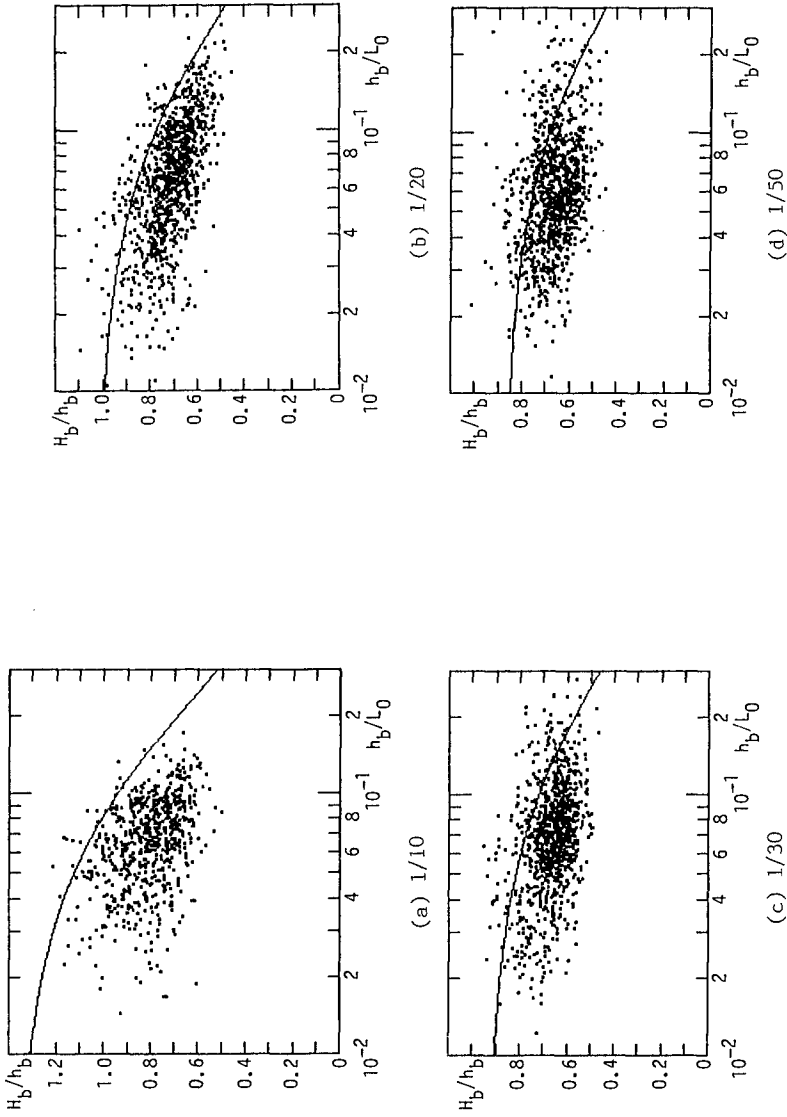

Fig.2 $H_b/h_b \sim h_b/L_0$ (ordinary definition for the water depth)

Fig.3 Definition of water depth d and h

in which a_c and a_t are the zero-crossing crest height and trough excursion (positive) respectively.

The data used in Fig.2 are reanalysed using the new definition of water depth in Fig.4. Considerable reductions in scattering are achieved for all cases. The reductions are prominent when the slope is mild. The solid lines in the figures are the experimental equations proposed in this study.

3.2 The breaking condition for irregular waves

Two types of breaking conditions for periodic waves have been proposed, which apply (1) the critical wave steepness and (2) the critical wave height water depth ratio respectively. Since the present experiments were carried out in the region $d_b/L_0 > 0.01$, the formulation following the former condition (1) was applied in this study. Following Goda's formulation for periodic waves (1970), we assume the breaking condition in the form,

$$H_b/d_b = A \{ 1 - \exp [-B \pi (d_b/L_0)(1+15 \tan^4 \theta)] \} (L_0/d_b) + C \quad (2)$$

in which θ is an angle of slope, and $A=1.7$, $B=1.5$ and $C=0$. In Goda's equation water depth is measured from the bottom to the still water level. Applying the least square method for the data in Fig.4, optimum values for A, B and C were calculated as follows.

$$H_b/d_b = 0.16 \{ 1 - \exp [-0.8 \pi (d_b/L_0)(1+15 \tan^4 \theta)] \} (L_0/d_b) - 0.96 \tan \theta + 0.2 \quad (3)$$

The solid lines in Fig 5 (and in Fig.4) show the experimental equations (eq.3) and the broken lines are Goda's breaking condition for periodic waves. Since the difference between the equations for the 1/30 and 1/50 slopes is very small and the equation for the 1/50 slope agrees well with the measurement on the 1/60 slope by Kuo and Kuo (1972) ($H_b/h_b=0.63$), the equation for 1/50 may be applicable for further mild slopes as in the case for periodic waves (Goda,1970).

The above equations were introduced using experimental data in the range $0.01 < d_b/L_0 < 0.3$, the application of these equations may be restricted to waves within the above range.

The breaking types were also investigated. However, no recognized

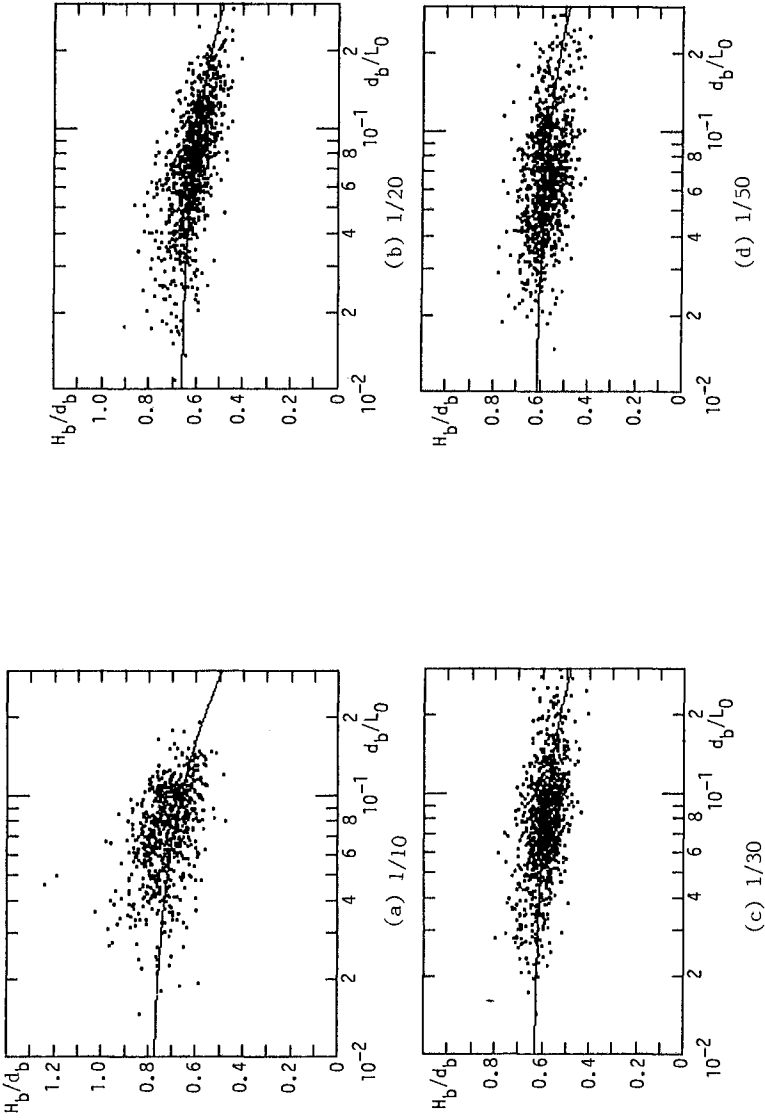

Fig.4 $H_b/d_b \sim d_b/L_0$ (new definition for the water depth)

Fig.5 Experimental equations (eq.3; solid lines)

property was found other than the property that the portion of plunging breaker increases with an increasing angle of the slope. The clarifications with other factors such as the surf-similarity parameter were not successful.

4. WAVE SHOALING

The measurement system applied was almost the same as that explained in the former section. Wave gauges were shifted to the offshore-side on the slope. The breaking point of waves were read off, at first, from the pictures recorded in the video-tapes. The corresponding zero-down-cross wave heights and periods at the wave gauge points were calculated from the wave profiles stored in the floppy discs. The figures in Fig.6 show the relation between the measured wave height and relative water depth d/L_0 on the slope of (a) 1/10, (b) 1/20, (c) 1/30 and (d) 1/50 respectively, in which H_0' and L_0 are wave height and period in deep water conditions, which were calculated substituting the wave height and period, measured by the most off-shore side wave gauge, in the small amplitude wave theory. In individual figures, data of about 1000 waves are plotted. The solid lines are the shoaling coefficient K_s of the small amplitude wave theory. Since the scatterings in the data are considerably large, the averaged relations of the above properties were compared with the theory. The figures in Fig.7 show the averaged relation between H/H_0' and d/L_0 . The circles are the averages of about 100, which distribute around them, and plotted individual mean positions. The vertical line attached to each circle shows the range of its standard deviation. The top figure (a) is for the data of $0.015 < H_0'/L_0 < 0.025$. The solid line shows the shoaling coefficient of the linear wave theory and the chain line also shows the coefficient of Shuto's theory (1974) which is introduced on the basis of the K-dV equation. The dotted line is the breaking condition for irregular waves newly proposed in section 3. The breaking condition for the 1/30 slope is representatively shown in the figure. Other breaking conditions for different slopes are very close to this line. The middle (b) and bottom

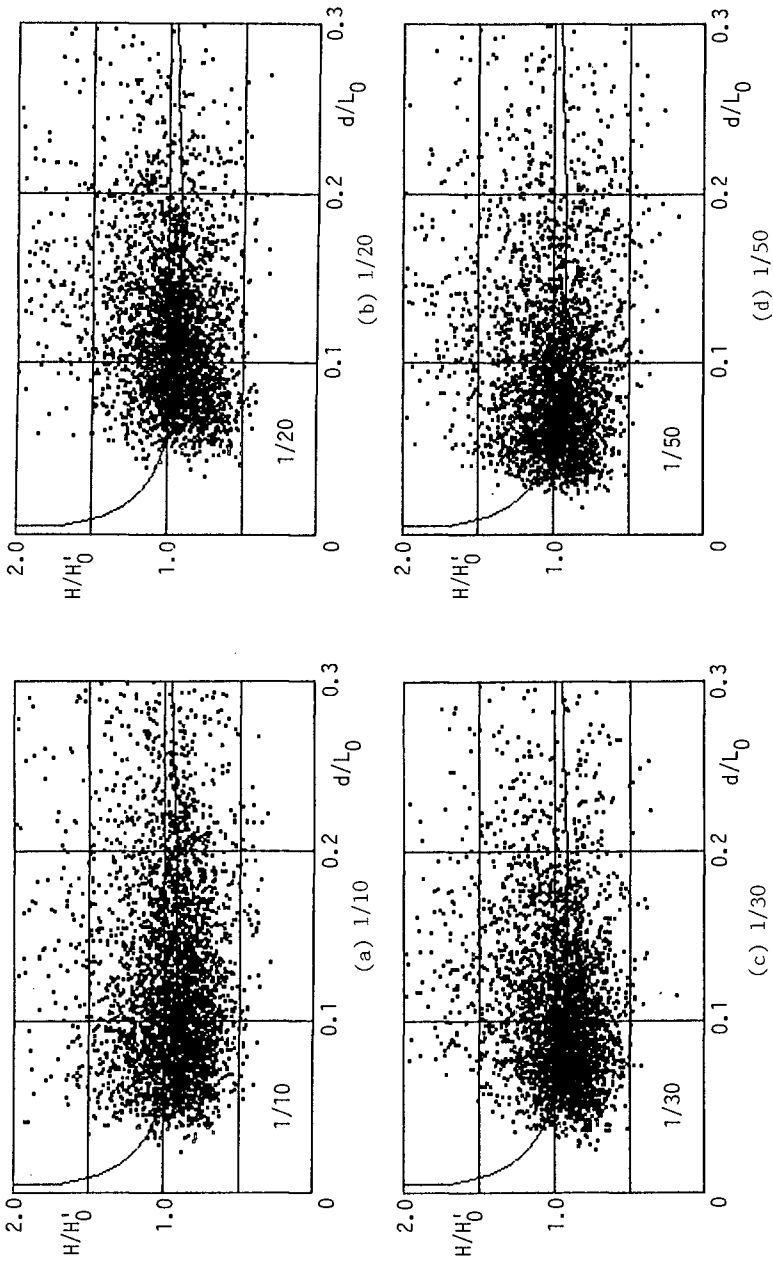

Fig. 6 $H/H_0' \sim d/L_0$

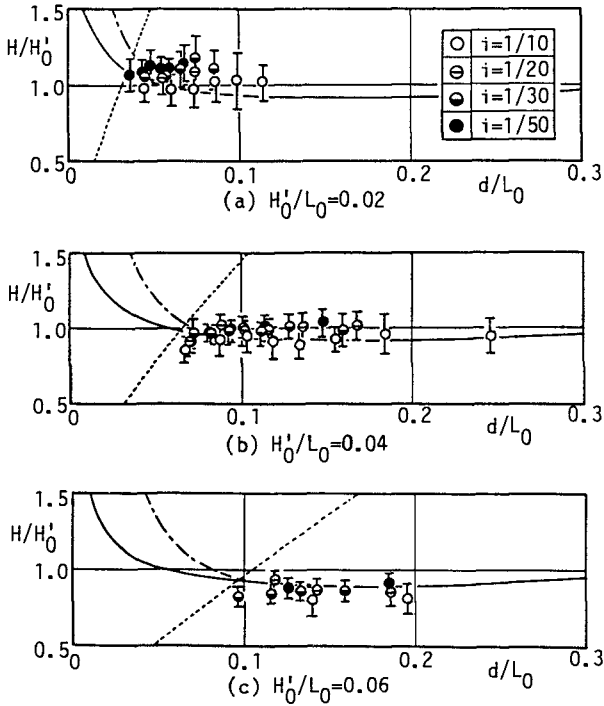

Fig.7 Averaged relations between H/H_0' and d/L_0

(c) figures are for the data of $0.035 < H_0'/L_0 < 0.045$ and $0.055 < H_0'/L_0 < 0.065$ respectively. The dotted lines are also the new breaking conditions for the slope of 1/30. No averaged data is plotted left of the dotted lines despite the slopes and H_0'/L_0 . For all slopes, a decreasing nature of plotted data with increasing wave steepness is observed. Furthermore data on the mild slope are slightly larger than those on the steep slope, especially in figure (a). However, the differences between the data and the theory are small (about 10% of the linear wave theory at most). Wave steepness may give a small effect on K_s . Especially, in the case of middle figure (b) ($H_0'/L_0 = 0.04$), in which the major portion of the data is included in this study, agreement between data and the theory is good despite the slope. The nonlinearity in the wave height change is compared with Shuto's theory in this study. His theory branches from the linear wave theory at Urcell number 30. The nonlinearity in the wave shoaling becomes, therefore, prominent from this point. However, the branch point and the intersections between the new breaking condition and solid and chain lines are very close to each other. This means that irregular waves break and start to decay before the difference between the linear and non-linear wave theories becomes prominent. For the waves with small steepness, however, the interval between the branch point and intersections becomes wider. For example, the distance is wider in figure (a) than in (c). However, the steepness of a significant wave in a fully developed sea condition distributes around 0.03 (Goda, 1975b). Thus, we may conclude that the shoaling property of the zero-down-

(a) 1/10

(b) 1/20

(c) 1/30

(d) 1/50

Fig.8 Wave height change after breaking

cross waves can be approximated by the linear wave theory as far as the present definition of wave breaking is applied and where the sea condition is a fully developed one. However, for waves with a smaller steepness than $H_0'/L_0=0.01$ the non-linear property in the shoaling may not be neglected in a very small region of d/L_0 . New investigations on the wave shoaling for zero-down-cross waves may be necessary.

5. WAVE HEIGHT DECAY AFTER BREAKING

The same measurement system as used in the former sections was applied in the experiments, although the whole system was shifted onto the shore side on the slope. The breaking points, at first, were read off from the picture recorded in the video-tape. The corresponding zero-down-cross wave heights and periods at the wave gauge points were also read off from the wave profiles stored in the floppy discs. The figures in Fig.8 show the wave height after breaking on the slope of (a) 1/10, (b) 1/20 (c) 1/30 and (d) 1/50, in which H_b and d_b are the wave height and water depth at the breaking point. Measured wave height decay of about 1000 are plotted in individual figures. The new definition of water depth also had a significant effect in reducing the scattering of the plotted data. To examine the mean tendency in detail, the data of every 0.1 interval of d/d_b were averaged and plotted in their mean position. Figure 9 shows the averaged relation between H/H_b and d/d_b on the slope of 1/30. The plotted data increase even after the breaking point. This is mainly due to the definition applied in this study since no practical energy dissipation takes place and wave height keeps increasing nature until it reaches the plunging point. There have been many studies which have adopted the maximum wave height to be the breaking wave height. However, this definition is difficult for practical measurements and the wave property at this point has not been clarified yet.

Fig.9 Averaged relation between H/H_b and d/d_b (1/30)

After reaching its maximum, the wave height starts to decay. The mean relations between H/H_b and d/d_b shore-side from this point are not uniform but have bends in all cases at around $d/d_b < 0.6$. Around the bend, the appearance of stable bores were observed in the experiments. Therefore, the process after breaking is divided into three different regions in this study. They are the shoaling region (from the breaking point to the point of maximum wave height), the plunging region (from the point of maximum wave height to the bend) and the bore region (from the bend to the shore). Although, the shoaling region reduces with decreasing slope angle, the data lies on straight lines approximately in individual regions despite the slopes. The wave height changes in these regions are approximated by straight lines in this study. Figures 10 (a) 1/10 and (b) 1/30 show the approximated regression lines for different wave steepnesses classified in the figure. Wave steepness brings a difference in the regression lines. This property is prominent in figure (a), but reduces in (b) considerably and becomes negligibly small in the case of 1/50 (although the figure is not shown in here). As explained in section 4, zero-down-cross wave steepnesses distribute around 0.03 when the sea condition is a fully developed one. In the region between $H_0'/L_0 = 0.01$ and 0.06, the difference in wave height change with respect to the steepness is small even in the case of 1/10. Therefore we may conclude that the effect of wave steepness on the wave height change after breaking is small if the sea condition is a fully developed one. Figure 11 shows the regression lines and averaged data for all cases. The regression lines are given by the equation,

$$H/H_b = A (d/d_b) + B \quad (4)$$

in which A and B are the constants given as follows in individual regions. (Subscripts S,P and B show that the values are for the shoaling, plunging and bore regions respectively.)

Fig.10 Effect of the wave steepness

Shoaling region:

$$A_S = -0.01 \tan \theta - 0.37$$

$$B_S = 1.0 - A_S \tag{5}$$

Plunging region: ($(H/H_b)_{\text{bore}}$, $(d/d_b)_{\text{bore}}$; see eq.(9))

$$A_P = 1.65 \exp(-2.3 \tan \theta)$$

$$B_P = (H/H_b)_{\text{bore}} - A_P (d/d_b)_{\text{bore}} \tag{6}$$

Bore region:

$$A_B = 0.72 \exp(6.11 \tan \theta)$$

$$B_B = 0.02 \tag{7}$$

The water depth and the wave height at the boundary between the shoaling and plunging regions (waves reach their maximum around this point) are given by

$$(d/d_b)_{\text{peak}} = (B_P - B_S) / (A_S - A_P)$$

$$(H/H_b)_{\text{peak}} = (A_P B_S - A_S B_P) / (A_P - A_S) \tag{8}$$

The water depth and wave height at the bend (the bore appears around this point) are given by

$$(H/H_b)_{\text{bore}} = 0.67 \exp(-3.1 \tan \theta)$$

$$(d/d_b)_{\text{bore}} = \{ (H/H_b)_{\text{bore}} - B_B \} / A_B \tag{9}$$

Fig.11 Regression lines for the wave height change after breaking

In the definition of eq.(5), data from a slightly offshore-side of the breaking point are applied in the calculation. On the shore-side of the breaking point, wave height change is affected by the mean water level change such as wave set-up and surf beat. The new definition applied in this study therefore determines the water depth as a sum of the still water depth and the (long period) mean water level displacement(s), consequently those effects of the (long period) mean water level changes are not included in these equations. In the practical application of these equations, the long period water level changes (Goda,1975b) should be introduced, although their properties are not investigated in this study.

6. CONCLUDING REMARKS.

The properties of zero-down-cross irregular waves on uniform slopes are examined experimentally. About 4,000 irregular waves of the Pierson-Moskowitz spectrum are analyzed in the study. The followings results were obtained:

- (1) The shoaling characteristics can be approximated by the linear wave theory.
- (2) H_p/d_b is about 30% smaller than that for periodic waves.
- (3) The process after breaking can be divided into three regions i.e. the shoaling, plunging and bore regions.
- (4) The experimental equations throughout the process are given.
- (5) A new definition of water depth which can largely reduce the fluctuation in the plotted data is proposed.

ACKNOWLEDGMENT: The authors wish to express their thanks to Mr T. Goto for his help in the experiment.

CHAPTER 30

Verification of numerical wave propagation models in tidal inlets

J.A. VOGEL, A.C. RADDER AND J.H. DE REUS*

The performance of two numerical wave propagation models has been investigated by comparison with field data. The first model is a refraction-diffraction model based on the parabolic equation method. The second is a refraction model based on the wave action equation, using a regular grid. Two field situations, viz. a tidal inlet and a river estuary along the Dutch coast, were used to determine the influence of the local wind on waves behind an island and a breaker zone. It may be concluded from the results of the computations and measurements that a much better agreement is obtained when wave growth due to wind is properly accounted for in the numerical models. In complicated coastal areas the models perform well for both engineering and research purposes.

1. INTRODUCTION

Sea waves approaching coastal regions can be influenced by a number of physical processes: shoaling, refraction by depth and current variations, diffraction, nonlinear effects, energy dissipation by wave breaking and bottom friction, and wave growth due to wind. In order to estimate inshore wave conditions from wave data available offshore, shallow water wave models should be able to account for these effects. Usually, numerical 2D shallow water wave propagation models include propagation and dissipation processes, while the influence of the local wind is often neglected (see e.g. Martin et al., 1987; Vincent and Carrie, 1988). For regions behind an island (c.q. peninsula) or a breaker zone the input from the local wind may be appreciable, and this effect cannot be accounted for by, e.g., taking a lower value of the friction factor. The purpose of this study is to verify two numerical models in this respect, with wave measurements in two field situations.

2. SHALLOW WATER WAVE MODELS

The performance of two shallow water wave models has been investigated:

- The model CREDIZ, which is based on the parabolic approximation of the mild-slope equation (Radder, 1979; Dingemans et al., 1984; Dingemans 1985).
- the model HISWA, which is based on refraction computations using a regular grid (Holthuijsen and Booij, 1986; Holthuijsen et al., 1988)

A mathematical formulation of these models is given below.

2.1 THE MODEL CREDIZ

The parabolic model CREDIZ describes the propagation of waves in coastal areas with non-uniform depth and current, in particular where both refraction and diffraction effects are important. The model is based on the following equation for monochromatic wave motion (for more details, see Dingemans, 1985):

$$(1) \quad \nabla \cdot (cc_g \nabla \varphi) + (k^2 cc_g + i\sigma(W + \nabla \cdot \vec{U}))\varphi = 0$$

where \vec{U} is the (steady) current-velocity vector, ∇ is the horizontal gradient operator ($\partial/\partial x$, $\partial/\partial y$), $\varphi(x, y)$ is the complex wave potential function, k the wave number, c and c_g the phase- and group velocity, σ the relative angular frequency, $i = \sqrt{-1}$ the imaginary unit, and W a dissipation coefficient, to be specified later on.

The absolute (ω) and relative (σ) frequencies are related by:

$$(2) \quad \omega = \sigma + \vec{k} \cdot \vec{U}$$

where σ is given by the linear dispersion relation:

$$(3) \quad \sigma^2 = gk \tanh kh$$

with g the acceleration of gravity and h the local depth.

In the parabolic approximation the assumption is made that the waves propagate mainly into a specific direction, say x .

Defining the operator M by $M = \frac{\partial}{\partial y}(\beta \frac{\partial}{\partial y})$ with $\beta = cc_g$

the parabolic approximation to equation (1) is given by:

$$(4) \quad \frac{\partial}{\partial x}(\sqrt{\beta k} \varphi + \frac{p_1}{k \sqrt{\beta k}} M \varphi) - i(k \sqrt{\beta k} \varphi + \frac{p_2}{\sqrt{\beta k}} M \varphi) +$$

$$+\frac{\sigma}{2\sqrt{\beta k}}(W + \nabla \cdot \vec{U})\varphi = 0$$

The coefficients p_1 and p_2 result from the approximation of pseudo-operators by differential operators and are related by:

$$(5) \quad p_2 = p_1 + \frac{1}{2}, \quad 0 \leq p_1 \leq \frac{1}{2} \quad (\text{optimal : } p_1 = \frac{1}{4})$$

As the wave-number vector \vec{k} in (2) is not exactly known beforehand, the relative frequency σ is approximated by:

$$\sigma = \omega - r k U_x$$

in which r is a reduction factor expressing the fact that the waves do not exactly follow the x-direction ($0 \leq r \leq 1$; standard value: $r = 0.9$).

The energy-dissipation term $W\varphi$ in equation (4) accounts for the effects of wave breaking, bottom friction and wave growth due to wind:

$$(6) \quad W\varphi = (W_b + W_f + W_g)\varphi$$

The dissipation function W_b due to wave breaking is computed according to the method of Battjes and Janssen (1978); see also Battjes and Stive (1985). For the dissipation function W_f due to bottom friction the method of Putnam and Johnson (1949) is used.

The effect of wave growth by wind is simulated by the (negative) dissipation term W_g :

$$(7) \quad W_g = -\frac{2c_g}{H_s} \frac{dH_s}{dx}$$

where $H_s = 2a$ is the significant wave height and a the wave amplitude. To compute the gradient dH_s/dx in (7), the growth curve of Krylov/Wilson is used (cf. Holthuisen, 1980; Krylov et al.,1976; Wilson, 1965):

$$(8) \quad \tilde{H}_s = \beta [1 - 1 / (1 + \alpha \sqrt{\tilde{x}})^2]$$

with $\tilde{H}_s = gH_s / V_x^2$, $\tilde{x} = gx / V_x^2$,
 V_x = component of wind speed in x-direction,
 α, β = coefficients ($\alpha \approx 0.006$, $\beta \approx 0.256$).

It is noted that the growth curve (8) is based on a parametric description of the wave spectrum; the effect of wave growth is assumed to be local, while

the period of the waves (due to the restriction to monochromatic waves) is assumed to be constant, equal to the peak period of the spectrum. Therefore, a spectral decomposition is not allowed when (8) is used.

The influence of the wave amplitude a on the propagation velocity is taken into account by setting the local depth h in the dispersion relation (3) equal to: $h = d + p_v a$ where d is the actual mean water depth and p_v is an adjustable parameter (standard value: 1). In the shallow water limit the celerity c of a solitary wave is obtained for $p_v = 1$, while in the deep water limit the linear expression for c is recovered.

The parabolic differential equation (4) can be solved in finite difference form, using a two-level, implicit numerical scheme on a rectangular grid. When dissipative physical effects are included (through the term $W\varphi$), the difference equations are linearized in a special way to ensure stability: in the case of $W < 0$, a positive diffusion is introduced in the (fully implicit) numerical scheme, in order to prevent non-linear instabilities in the early stage of wave growth due to wind. In practice, fairly accurate solutions have been obtained for values of grid spacings Δx and Δy according to: $\Delta x/L \leq 1/4$; $\Delta y/L \leq 1/6$, where $L = 2\pi/k$ is the local wave length.

The solution of equation (4) requires as initial conditions the amplitude, period and direction of the incident wave field; along the lateral boundaries, the wave field is generally not known, and an approximate boundary condition (reflecting or partially absorbing) may be applied. However, for instance in case of strong wave-current interactions, these conditions give not the right description; therefore, the computational grid should be chosen sufficiently large, to avoid disturbances of the wave field in the region of interest.

2.2 THE MODEL HISWA

The model HISWA accounts for refractive propagation of shortcrested waves over arbitrary bottom topography and current fields. The model is based on the action balance equation:

$$(9) \quad \frac{\partial A}{\partial t} + x_i \frac{\partial A}{\partial x_i} + \dot{k}_i \frac{\partial A}{\partial k_i} = T$$

where $A(\vec{k}, \vec{x}, t)$ denotes the wave action density, $x_i \equiv \frac{dx_i}{dt} = \frac{\partial \Omega}{\partial k_i}$ is the group velocity and $\dot{k}_i \equiv \frac{dk_i}{dt} = -\frac{\partial \Omega}{\partial x_i}$ is the rate of change of wave number due to refraction. The right hand side denotes the local change of action density, e.g. by dissipation. The dispersion relation is given as $\omega = \Omega(\vec{k}, \vec{x}, t)$, see (2) and (3). For simplicity we assume in this derivation that there is no ambient current; see Dingemans et al. (1986) for the current case. In the model the simplifying assumption of stationarity, i.e. no explicit dependence on time, is made. Then

Ω is a Hamiltonian for the vectorfield (x_i, k_i) . Transforming from (\vec{k}, \vec{x}) -space to the $(\vec{x}, \omega, \vartheta)$ -space with ϑ the wave direction and introducing the absolute energy density \tilde{E} by $\tilde{E} = A\omega$, one obtains after integration over ω between 0 and ∞ :

$$(10) \quad \frac{\partial}{\partial x} [\omega^A \cdot A^{(o)} \cdot \bar{c}_g \cos\vartheta] + \frac{\partial}{\partial y} [\omega^A \cdot A^{(o)} \cdot \bar{c}_g \sin\vartheta] + \frac{\partial}{\partial \vartheta} [\omega^A \cdot A^{(o)} \cdot \bar{c}_\vartheta] = T_1$$

where the mean quantities ω^A , $A^{(o)}$, \bar{c}_g and \bar{c}_ϑ are defined by:
 $A^{(o)}(x, y, \vartheta) = \int_0^\infty A(x, y, \omega, \vartheta) d\omega$; $\omega^A(x, y, \vartheta) = \frac{1}{A^{(o)}} \int_0^\infty \omega A d\omega$;
 $E^{(o)} = \omega^A \cdot A^{(o)}$; $\bar{c}_g = \frac{1}{E^{(o)}} \int_0^\infty \tilde{E} \cdot c_g d\omega$; $\bar{c}_\vartheta = \frac{1}{E^{(o)}} \int_0^\infty \tilde{E} (c_g - \frac{c}{2}) \frac{1}{h} \frac{\partial h}{\partial n} d\omega$;
 $T_1 = \int_0^\infty \omega T d\omega$; $c_g = \frac{\partial \Omega}{\partial k}$; $c = \frac{\omega}{k}$; $\vec{n} = (-\sin\vartheta, \cos\vartheta)$.

Using Leibniz' rule and rewriting the result, a second equation is obtained:

$$(11) \quad \frac{\partial}{\partial x} [A^{(o)} \cdot \bar{c}_g \cos\vartheta] + \frac{\partial}{\partial y} [A^{(o)} \cdot \bar{c}_g \sin\vartheta] + \frac{\partial}{\partial \vartheta} [A^{(o)} \cdot \bar{c}_\vartheta] = \frac{1}{\omega^A} [T_1 - A^{(o)} \cdot \bar{c}_{g,i} \cdot \frac{\partial \omega^A}{\partial x_i}]$$

Equation (10) and (11) are the basic equations for HISWA. The source term T_1 is implemented as $(\omega^A/\sigma^A) \cdot S^{(o)}$, where $S^{(o)}$ denotes the local chance of energy and $\bar{c}_{g,i} \cdot \frac{\partial \omega^A}{\partial x_i}$ is interpreted as the change of the frequency ω^A , which is prescribed as a function S_ω of the local data.

The source terms $S^{(o)}$ and S_ω represent the effects of wave breaking, bottom friction, wind wave generation, and wave blocking on an opposing current. The dissipation due to wave breaking and bottom friction is modelled by the same methods as used in the CREDIZ model. The formulation is extended to random waves with directional distribution by assuming that the dissipation per direction is proportional to the energy density at that direction. The formulation of the source term for wave generation by wind is based on available expressions giving the total energy and the frequency averaged over the whole spectrum, as functions of fetch and wind speed. Details can be found in Holthuijsen et al. (1988).

The first order partial differential equations (10, 11) can be solved on a regular grid in (x,y,ϑ) -space, with the x-direction parallel to the main direction of the wave field. In the present version of the model, a leapfrog finite difference scheme is used, together with appropriate boundary conditions. As initial conditions, the wave height, period, direction and spreading (or the directional spectrum) of the incident wave field are required.

3. COMPARISON WITH FIELD MEASUREMENTS

The present verification study concerns two field situations:

- the tidal inlet of Texel,
- the estuary of Haringvliet.

Results of the comparison are presented below.

3.1 THE TIDAL INLET OF TEXEL.

This is a strait connecting an ebb tidal delta at the North Sea side with the area of interest, the Wadden Sea, at the other side (see fig. 1). The entrance of the inlet is sheltered by a shoal, which is flooded only during very high tide. The effect of the local wind is thus dominant, while the influence of the tidal current is of secondary importance.

Wave data are available from five locations, of which we used three in this paper:

EIERLAND, located offshore in the North Sea, to provide the input wave conditions for the models;

BOLLEN and MALZWIN, located in the Wadden Sea, to verify the numerical models.

Apart from the wavestaff at MALZWIN, waverider buoys were employed at the measurement locations. Measurements were selected from the period 11 October 1981 to 11 March 1982, using the criteria:

- wind direction ranging from 220° to 300° (\pm SW to NW);
- wind speed higher than 6 m/s.

In table 1 thirteen selected cases are shown which provide the input wave parameters measured at the offshore buoy. In each case, the tidal current is represented by one of four characteristic stages: maximum ebb, slack tide ebb-flood, maximum flood, slack tide flood-ebb (see figs. 2 - 5). The wave direction of the incident wave field is assumed to be equal to the wind direction, given in table 1.

The bottom topography is represented by a depth array of 136×104 grid points, with a spacing of 250 m. At the same grid points, the components of the current velocities are given. Further details can be found in: den Adel (1988). The results of the computations of the models are compared with the measurements in table 1, and a scatter plot is given in fig. 10.

From the computations we draw the conclusions:

- the influence of the local wind is most important in this area: when wave growth due to wind is not accounted for, the computed wave height reduces to values less than a few percent of the incident wave height. This is mainly due to -besides breaking on the shoal- diffraction of wave energy in the Wadden Sea: swell decays here rapidly.
- the influence of the tidal current (with velocities up to 1.5 m/s) can be appreciable: differences of more than 50% may be found, comparing cases

with and without current; in the maximum-ebb case nr. 13, a tunneling of waves does occur (see figs. 6, 7 and 8, 9).

- the influence of the waves on the North Sea is very small; only during maximum-ebb-flow and if the waves come from the South-East more than a few percent of the input wave height remains at the Wadden Sea.
- the change in significant wave period plays a role: at lower periods, the wave-current interaction is stronger, while refraction by depth and bottom friction are weaker. This partially explains the differences in the results of the model computations.

Remarks

1. The present version of the model HISWA does not perform well in case of very small directional distribution; therefore, the model should be used with care when swell-components are present in the wave field.
2. The model CREDIZ shows a sensitive dependence of the side-boundary conditions of the computational grid, in case of strong tidal currents crossing these boundaries; care should be taken that the wave field in the area of interest is not disturbed, by choosing the computational grid sufficiently large.

3.2 THE ESTUARY OF HARINGVLIET.

This area is characterized by a shoal called Hinderplaat which falls partly dry during low tide, a region with nearly straight isobaths offshore the shoal, and a complicated bottom geometry inshore (see fig. 11). In the vicinity of the shoal, wave breaking is the predominant physical process; after this breaking, the wind may enhance the wave height appreciably along a distance of a few miles behind the shoal.

Wave data are available from a measurement campaign during the autumn of 1982 (for details, see Dingemans, 1983; Dingemans et al. 1984). Recently, this data set has been used extensively to test the performance of numerical shallow water wave models (Martin et al. 1987; Vincent and Carrie, 1988). However, energy input from the wind is not included in these models.

In order to test the effect of the local wind, the storm situation of 14 - 15 October 1982 was selected. For a fair comparison with previous CREDIZ results, the same cases as described by Dingemans (1983) were used, with the same input parameters (e.g. the 1981 - bottom topography, consisting of 88 x 117 grid points with spacing of 250 m, and a bottom friction factor $f = 0.005$ instead of the more appropriate 0.01). Further input conditions were:

- wind direction ranging from 300° to 320° ;
- wind speed ranging from 12.9 to 16.5 m/s;
- peak period ranging from 7.1 to 8.3 s (at the Wavec buoy).

The results of the computations are shown in table 2, where the relative error δ is defined by $\delta = (H_s - H_{sm})/H_{sm}$. For each of the six cases, the bias b and the rms-deviation ϵ_{rms} are given in table 3.

By definition, $b = \sum (H_s - H_{sm}) / \sum H_{sm}$;

$$\epsilon_{rms} = [n^{-1} \sum (H_s - H_{sm})^2]^{1/2} / [n^{-1} \sum H_{sm}].$$

The following conclusions may be inferred:

- the model CREDIZ (and, to a lesser extent, also HISWA) performs much better when wave growth due to wind is properly accounted for, especially at low water levels.
- while HISWA performs well at E-75, the wave-staff far behind the shoal, CREDIZ still gives too low values of H_s there; this is probably due to the effect of directional spreading of the wave field, and the transfer of energy between spectral components, resulting in a lowering of the significant wave period, and less dissipation due to bottom friction.
- the computed wave height at WR4, just behind the Hinderplaat, is still too low for low water levels; this is probably due to (local) set-up of the mean water level by waves, which effect is not included in the models.
- at the other locations (mainly at WR5 and WR6), the process of spectral saturation (white-capping) is of importance. This process is simulated in the models by the dissipation method of Battjes and Janssen (1978) for random breaking waves, where breaking is caused also by exceedence of steepness.

4. CONCLUSIONS

A verification study of two wave propagation models has been made, using field data in which the influence of the local wind is significant. In spite of the distinct differences between the models (e.g. CREDIZ is a monochromatic model including diffractive effects, while HISWA is a variable frequency model with directional spreading effects), both models perform equally well in complicated coastal areas. (For specific conclusions, see §3.1 and §3.2).

There remains the problem to describe in a more fundamental way changes in wave frequency, especially in shallow water (for instance, by the undular bore model; see Dingemans and Battjes, these Proceedings). This is important when the models are used in sediment transport studies.

CHAPTER 31

KINEMATICS AND RETURN FLOW IN A CLOSED WAVE FLUME

Jerald D. Ramsden¹, AM. ASCE

John H. Nath², F. ASCE

ABSTRACT

Stokes (1847) showed that finite amplitude progressing waves cause a net drift of fluid, in the direction of wave motion, which occurs in the upper portion of the water column. In a closed wave flume this drift must be accompanied by a return flow toward the wave generator to satisfy the conservation of mass. This study presents Eulerian velocity and water surface measurements soon after the onset of wave motion from 12 locations in a large scale flume. Waves with $.67 \leq kh \leq 2.29$ and $.09 \leq H/h \leq .39$ were produced in a water depth of 3.5 meters. Superimposing the return flow theory of Kim (1984) with seventh order stream function theory is shown to improve the velocity predictions. The measured return flows are a function of time and depth and agree with Kim's theory as a first approximation. The mean water surface set-down agrees with the theory of Brevik (1979) except for the nearly deep water waves.

INTRODUCTION

Periodic progressing gravity waves confined in a closed wave flume cause a longitudinal circulation to develop. This circulation is driven by mass transport [Stokes (1847)] in the direction of wave propagation and results in a return flow toward the wave generator. The circulation in closed flumes has been extensively studied

¹Graduate Student, W. M. Keck Laboratory, California Institute of Technology, Pasadena, CA

²Professor Emeritus, Department of Civil Engineering, Oregon State University, Corvallis, OR.

in Lagrangian coordinates while few Eulerian measurements have been published. Many studies of the Eulerian water particle velocities and wave force measurements on fixed structures are carried out in closed wave flumes. Measurements from these studies will include the effects of the circulation. The free waves, beach reflections, wind, flume geometry, and the initial conditions may also differ between the wave flume and the ocean.

Studies in flumes are often conducted within a few or several waves after the onset of wave motion to minimize reflections and oscillations characteristic of the flume geometry. The objective of this study is to characterize the behavior of the return flow during this time period.

Two distinct methods have been used to predict the return flow. In one method, inviscid wave theory is used to compute a volume flux due to mass transport. Then a steady uniform return flow (R_c) is superimposed on the wave theory, such that the volume flux due to the return flow cancels the flux from the mass transport. This method was used on stream function wave theory by Dalrymple (1976) and on Stokes' second through fifth order wave theories by Kim (1984). The other was pioneered by Longuet-Higgins (1953) who solved the 'conduction equation' assuming a viscous fluid. He obtained an explicit solution for the circulation in a closed two dimensional flume. The conduction solution predicts parabolic return flow profiles over depth in contrast to the uniform return flow assumed with the inviscid theory. Return flows predicted from inviscid theory should provide reasonable results for flow outside the boundary layers during the first several waves as discussed by Longuet-Higgins (1953) and as shown in this paper. Longuet-Higgins' method provides reasonable predictions near the bottom boundary layer [Russel and Osorio (1958)] and throughout the water column when the wave motion has continued for several hundred wave periods [Bullock and Short (1985)].

To the authors' knowledge only Nath (1978) and Kim (1984) have published Eulerian return flow measurements which were collected soon after the start of wave motion. Both of these authors used the same flume, water depth, and approximately the same wave conditions as used in this study. Both their results contained considerable variability. Due to this variability, Kim found that Longuet-Higgins method and the one developed by him based on

Stokes fifth order wave theory yeild similar errors when compared with both their measurements.

THEORY

As discussed by Longuet-Higgins (1953), when the wave motion starts, the flow is everywhere irrotational except in the boundary layers along the flume walls, the bottom, and the free surface. The boundary layer thickness δ along the flume bottom is approximately $(2\nu/\omega)^{1/2}$, where ω is the angular frequency of the wave motion and ν is the kinematic viscosity of water. For the conditions of this study, δ is on the order of a few millimeters. If the boundary layer thickness on the sides and surface is of this same order, then approximately two tenths of one percent of the flume cross section lies within the boundary layers. Thus, inviscid wave theory should adequately predict the mass transport volume flux and the return flow within the first several wave periods.

The results of Kim's (1984) return current model [see also Kim, Hudspeth, and Sulisz (1986)] based on Stokes second and fifth order wave theories are presented in Figure 1, where T is the wave period, h the water depth, H the wave height, $L_o = gT^2/2\pi$ the deep water wave length where g is the gravitational constant, $C_o = L_o/T$ the deep water wave celerity, and R_c the theoretical return flow. His model, based on the assumption that the return flow is steady and uniform, is the first to include the contribution from the free waves. The fifth order return flow theory is used throughout this paper.

Kim, Hudspeth, and Sulisz (1986) showed that a complete second order solution of the wavemaker boundary value problem requires a time independent potential in addition to the Stokes wave, a free wave, and a series of evanescent waves which were treated earlier by others. The evanescent waves decay with distance from the wave generator and do not propagate. Figure 1 is only valid beyond 3 water depths from the wave generator where the evanescent waves have decayed to a negligible value. The free wave is forced at twice the wave generator frequency. Since the free wave obeys its own dispersion relation, it propagates slower than the Stokes wave which causes the waveform to be nonpermanent along the flume [Buhr Hansen and Svendsen (1974)].

In this study seventh order stream function wave theory is linearly superimposed with Kim's return flow theory. Studies by Chandler and Hinwood (1982) and Dalrymple (1976) indicate that

Figure 1: Return current in a closed wave flume for a flap type wave-maker computed from Stokes wave theory [adapted from Kim(1984)].

small currents, like those due to the return flow, can be linearly superimposed with wave theory since the nonlinear interaction effects are quite small.

From the concept of the radiation stress, Longuet-Higgins and Stewart (1964) showed that waves propagating into still water may cause a change in the mean water surface elevation. The mean water levels in this study are compared with a theory presented by Brevik (1979). He derived an expression for the water surface set-down under a packet of waves propagating in water of a constant

depth. The wave packet was assumed to have a Gaussian wave height distribution in space and a narrow banded wave number spectrum.

EXPERIMENT

The wave kinematics were measured in the O. Howard Hinsdale Wave Research Laboratory wave flume (Fig. 2.) during February 1985. The flume is 3.94 m. wide, 96.5 m. long, and has walls of smooth concrete. The wave board is hinged at the flume bottom and driven in a sinusoidal motion by a hydraulic piston.

Four Marsh McBirney Model 711 current meters were used to measure the horizontal and vertical velocities. They operate on the principle of Faraday's law of electromagnetic induction. Each probe is a 2.5 cm. diameter cylinder with a length of 25 cm. and senses the velocities in a plane perpendicular to its axis. Over the frequency range of interest in this study, 0.0 to 2.0 Hz., the current meter electronics behave as a linear first order filter, Ramsden (1987). Both axes of each meter were calibrated using two independent methods which gave complimentary results.

The water particle velocities were measured in twelve locations for each wave condition. The water depth was 3.77 m at the test section during all the measurements. The 25 wave conditions were repeated three times with the meters in different arrangements. Figure 2 shows the three stations where the measurements were collected. Two current meters were placed on each side of the flume for arrangement no. 1 and no. 2. For meter arrangement no. 3 all the current meters were placed on the same side of the flume with two at station no. 1 and two at station no. 3. Three of the current meters were mounted .33 meters from the flume wall while the other was .98 meters from the wall. All the measurements were collected within $-.74 \leq z/h \leq -.04$, where z is the vertical coordinate with its origin at the water surface and directed positive upward.

The wave conditions were obtained by using five different wave generator strokes for each of five wave periods. The wave periods were 2.5, 3.7, 4.6, 5.3, and 6.0 seconds. The stroke was set to obtain wave heights ranging between .33 m. to the maximum possible height for each wave period. The maximum wave heights ranged from 1.07 meters at $T=2.5$ sec., up to 1.37 m. at $T=3.7$ sec., then down to .94 m. for the 6.0 sec. waves. The water surface profile (η) was measured with sonic wave profilers at the center of the flume

Figure 2: The wave flume at the O. Howard Hinsdale Wave Research Laboratory on the Oregon State University Campus (all dimensions are in meters).

in each cross section containing current meters. The measurements were collected for 14 wave periods beginning with the initial wave disturbance at the current meter locations. The data were recorded digitally at 256 samples per wave period. Before the wave generator was started, 256 samples were collected which are averaged to establish the still water level and the velocity reference. For some of the runs during the first current meter arrangement, an additional block of 14 wave periods of data was collected while letting the wave generator run continuously. This second data block began from 30 sec. to 120 sec. after the end of the first data block.

RESULTS

Out of 525 velocity records 439 were clean and consistent. For the other 86 records there were some problems which included very noisy or erratic reference measurements, voltage jumps during sampling, and some runs where one or two of the meters gave no response.

Figures 3a through 3c show a comparison of the horizontal velocity measurements vs. theory under the wave peak (positive velocities) and trough (negative velocities). Measurements from the maximum wave heights obtained at each wave period are shown. The questionable measurement in Fig. 3a is from a current meter that was intermittently submerged and gave quite low velocities, relative to the other measurements, for the 2.5 sec. waves. This may reveal a minimum amount of submergence time for the model 711 to record the actual velocity when placed above the wave trough. The questionable measurements in Figures 3b and 3c are from a current meter which was working intermittently.

Figure 3a shows velocity profiles at the crest and the trough of a fairly deep water wave. The data from this study and those from Kobune (1978) and Jensen (1978) agree quite well even though they were collected at widely different times and with different types of current meters. Jensen and Kobune used a water depth of 3.35 m. instead of the 3.50 m. of this study.

The measurements follow the theoretical trends quite well although there is some variability which tends to increase with the wave length. This variability is most likely due to both the free waves and the beach reflections. Nath measured the beach reflections with the same flume geometry in 1982. He found the reflection coefficient to be independent of the wave height and to range from

Figure 3: Nondimensional horizontal velocity under the wave crest and trough vs. relative depth. Figures 4a, b, and c show the results of Ramsden (\square) electromagnetic current meters, (—) stream function theory, (---) stream function theory with return flow theory, and (\circ) questionable measurements. Figure 4a also shows the measurements of Jensen (1978) (\circ) propellor meter and Kobune (1978) (\blacktriangle) hot film anemometer, (\triangle) propellor meter.

5% to 10% for the 2.5 sec. to 6. sec. waves, respectively. The free waves may be about as large as the second order Stokes wave as shown by Buhr Hansen and Svendsen (1974). The data of this study and that of Bullock and Short (1985) showed that the amplitude of the second harmonic of η is typically 10%, and at most 25%, of the fundamental harmonic. The second harmonics of 25% most likely include a contribution from both the free wave and the Stokes wave. Thus, the free wave is probably at most 12% of the Stokes first harmonic. Since the free and reflected waves travel in opposite directions, their effect on the horizontal velocity will be the largest where the crest of one coincides with the trough of the other. With a reflection of 10% and a free wave of 12% this effect should be limited to $\pm 22\%$ of the Stokes first harmonic. To correct the theory for the reflection and the free wave, one must know their amplitude as well as their phase relative to the Stokes wave.

Since the free wave celerity is smaller than the Stokes wave celerity, one can compute the time lag between the leading edge of the two wave groups for any location along the flume. For station 1 the lag between the groups is 7.5 and .9 Stokes wave periods for the 2.5 sec. and 6. sec. waves, respectively. Since the measured velocities plotted in Fig. 3 are from about the fourth wave, the results in Fig. 3a from this study were most likely obtained before arrival of the free wave. Since the free waves have not arrived and the reflections are about 5%, the agreement between measurements and predictions is very close. As the wave length increases one should expect more variability in the measurements, due to the free and reflected waves, as shown in Figures 3b and 3c.

In Fig. 3a the ratio of the return flow to the maximum velocity increases with increasing depth due to the attenuation of the water wave velocity. As a result, the return flow reaches 26% of the maximum measured velocity at a relative depth of $z/h = -.74$. From all the measurements in this study, the stream function theory modified for the return flow predicted the maximum measured velocities within $\pm 15\%$ during 85% of the runs. A few measurements were from 30% to 50% less than predicted, however most of these were associated with questionable current meter response.

The mean wave profile ($\bar{\eta}$) and the return flow (\bar{u}) are shown for the largest 2.5 sec. wave and 5.3 sec. wave in Figures 4a and 4b, respectively. The mean values were computed at specific points in

Figure 4: Nondimensional water surface profile, mean water surface, and return flow vs. time. Wave conditions: (a) $T=2.5$ sec. ($T\sqrt{g/h} = 4.18$), $H=1.07$ m. ($H/h = .304$); and (b) $T=5.3$ sec. ($T\sqrt{g/h} = 8.87$), $H=1.07$ m. For $-\bar{u}/R_c$ the various lines correspond to (—) $z/h = -0.74$, (---) $z/h = -0.33$, and (- - -) $z/h = -0.32$.

Figure 5: Mean and standard deviation of the normalized return flow vs. the relative wave height for all the runs. In the bottom of the figure the theoretical return flow is shown at each wave height for the 2.5 sec. and 6. sec. waves.

time by averaging the record over a wave period which is centered at that point. This average is then computed at 32 points per wave period over the entire record. The water surface profile is shown on the top of each figure and the time scale is reference to the start of the measurements. The break in the time scale represents the amount of time elapsed between the two blocks of data.

For the nearly deep water wave (Fig. 4a), the return flow at relative depths of $-.33$ and $-.32$ show a gradual rize to zero during the first data block, while settling to nearly constant values in the second block. This was characteristic of the 2.5, 3.7, and 4.6 sec. waves, although the unsteadiness in the first data block was quite variable from one run to another. Figure 4b is characteristic of the 5.3 and 6. sec. waves, where the return flow is fairly stable from the start except for a subharmonic response which may be due to long waves excited at these wave periods.

Figure 6: Mean and standard deviation of the nondimensional return flow, averaged over the wave height, vs. the relative depth for each wave period.

Surprisingly, $\bar{\eta}$ was positive for all the 2.5 second waves (Fig. 4a) and the smallest 3.7 sec. wave. For all the other wave conditions (Fig. 4b) $\bar{\eta}$ was negative in accordance with the theory of Brevik (1979) which always predicts a negative $\bar{\eta}$. For the shorter waves, $\bar{\eta}$ tended to stabilize much more rapidly and had no large jumps like that in (Fig. 4b) at $t/T=5$ which were characteristic of the longer waves records. In Figure 4b the η record shows the time lag between the free and Stokes waves, since the hump in the wave

Figure 7: Mean water surface set-down vs. kh . The mean and standard deviation of the measurements are compared with the theory of Brevik (1979) which is shown as a solid line.

trough takes a few wave periods to develop.

Figure 5 shows \bar{u}/R_c vs. the relative wave height for all the runs. The data were grouped according to the wave period. The measured horizontal velocity was averaged over eight waves to compute \bar{u} . The average was started at about the third wave of constant height. This figure shows that on the average, Kim's theory predicts the return flows within about 18%. The smallest return flows had large variability which may be due to the numerical sensitivity of dividing two small numbers, and it may indicate a lower limit of the current meters sensitivity.

The values of $-\bar{u}/R_c$, averaged over the wave heights at each vertical location are shown for each wave period in Figure 6. The measured return flow was computed as in Figure 5. There is considerable vertical structure to the return flow which tends to diminish as the wave period increases. Due to this structure, Kim's theory overpredicts the return flow above $z/h = -0.4$, while it tends to underpredict the return flow below this level. It may be that if one could extend this trend, the return flow would become zero somewhere near the mean water surface and would be positive above

that point, becoming zero again at the wave crest elevation.

Figure 7 shows the normalized wave set-down plotted against kh . The mean water surface elevations were computed by averaging the last eight waves of the first 14 wave period data block. The measurements follow Brevik's (1979) theory closely for the longer waves, but as the wave length becomes smaller his theory tends to zero while the measurements show a wave set-up.

CONCLUSIONS

There is a return flow under large amplitude waves. For the conditions of this study Kim's theory is a good first approximation except very near the mean water surface. Including Kim's return flow model with stream function wave theory improves the agreement between the measured and predicted velocities. The return flow is a function of time and depth. Brevik's theory predicts the water surface set-down closely except for the nearly deep water waves. No dependence of the return flow or the water surface set-down with horizontal position could be determined from these data.

CHAPTER 32

A HYDRODYNAMIC MODEL FOR COMPUTER AIDED HARBOUR ENGINEERING

J.L. Monsó*, A.S.- Arcilla* and J.P. Sierra*

Abstract

Coastal Hydrodynamic analyses are basic for the planning and assessment of activities in that area. An important application of these analyses is harbour lay-out and location. In this paper, hydrodynamic results of a numerical model based on Boussinesq-type equations are presented in the issue of Computer Aided Harbour Engineering. This model achieves overall second-order accuracy and has efficient modules of pre- and post-processing of information. The model has been used as a CAD tool for the planning and design of Spanish harbours. Its flexibility and economy of operation allow the model to be used, in the future, as a module of a global expert system for CAD harbour lay-out. This global expert system will provide a fully automatic design process. The output of this system will consist in the final optimized harbour configuration, considering all imposed constraints and requirements.

1. Introduction

Computer-aided harbour engineering has become a subject of considerable economic importance. The inputs for the design process are an initial harbour geometry, expected environmental conditions and a set of lay-out design specifications. Hydrodynamic descriptions of wave propagation, sea level oscillations and associated currents are provided by numerical 2-D models, usually based on shallow water Boussinesq-type equations. Analyses of obtained results are now performed by an expert engineer. From here, the appropriate modifications in geometry are carried out by an iterative process until a final optimized configuration is reached.

In this paper both the numerical model describing the flow and the expert system designing the optimal lay-out configuration (in lieu of the engineer) are presented. The first one is being used for commercial applications while the second one is under development. Nevertheless, the general structure of the system has already been defined.

2. Hydrodynamic Model Equations

The model is based on Boussinesq-type shallow-water equations.
*Maritime Engineering Laboratory.

quations. They are similar to the Airy equations but include an additional term due to the vertical acceleration effect which, in turn, induces a non-hydrostatic pressure distribution. Alternatively, these equations include frequency-dispersion effects to the leading order.

The governing equations are obtained applying a perturbation technique to the vertically integrated continuity and momentum equations (Peregrine, 1967). From the perturbation analysis different sets of equations may be obtained for various orders of approximation. It is important to point out that the various long-wave equations available are always simplifications of the actual problem (prototype) with a degree of approximation depending on the physical characteristics of the phenomenon considered. These mean, in turn, different truncation errors that may be evaluated in terms of dimensionless parameters, ϵ and σ .

$$\epsilon \equiv \frac{\eta}{h} \quad (1)$$

$$\sigma \equiv \frac{h}{L} \quad (2)$$

in which η is the free-surface elevation, h is the water depth and L is a typical wave length. These parameters define the URSELL parameter, which characterizes the relative importance of nonlinearity and dispersion.

$$Ur = \epsilon/\sigma^2 \quad (3)$$

Most of the hydrodynamic conditions that can be found inside of a harbour are due (associated) to short-waves with $Ur = O(1)$, i.e. $\epsilon = O(\sigma^2)$. In such cases, Boussinesq equations result from the vertical integration of mass and momentum conservation equations, with an associated error of $O(\epsilon^2)$ or more generally $O(\epsilon^2, \epsilon^2, \epsilon^4)$.

The set of non-linear differential equations to be discretized are similar to the ones used by other authors (Abbot, 1981), (Hauguel, 1980) and have been developed with detail elsewhere (S.-Arcilla and Monsó, 1985). The following simplifying hypotheses are required in the derivation:

1. Newtonian, isotropic and incompressible fluid.
2. Slowly varying bottom topography.
3. Water depth is always small with respect to the wave length (i.e. $\sigma^2 \ll 1$).

The main variables of the problem (velocities, pressure and free-surface elevation) are expressed as power series:

$$f = f_0 + \epsilon f_1 + \epsilon^2 f_2 + \dots \quad (4)$$

in which f is any of these variables with the exception of vertical velocities that are written as:

$$\omega = \sigma(\omega_0 + \epsilon\omega_1 + \epsilon^2\omega_2 + \dots) \quad (5)$$

The resulting vertically integrated equations are:

1. Mass conservation:

$$\frac{\partial \eta}{\partial t} + \nabla \vec{Q} = 0 \tag{6}$$

2. Momentum conservation:

$$\frac{\partial \vec{Q}}{\partial t} + \frac{Q}{H} \nabla \vec{Q} + (\vec{Q} \nabla) \frac{\vec{Q}}{H} + gH \nabla \eta = \frac{1}{2} Hh \frac{\partial}{\partial t} \nabla (\nabla_h \vec{Q}) - \frac{1}{6} Hh^2 \cdot \frac{\partial}{\partial t} \nabla (\nabla \frac{\vec{Q}}{H}) \tag{7}$$

in which:

$$\vec{Q} = (p, q) \tag{8}$$

$$p = \int_{-h}^{\eta} u dz \tag{9}$$

$$q = \int_{-h}^{\eta} v dz \tag{10}$$

$$H = \eta + h \tag{11}$$

$$\nabla = (\partial / \partial x, \partial / \partial y) \tag{12}$$

Fig.1: Definition sketch.

To simplify the resulting expressions, terms due to Coriolis forces, wind and bottom stresses, atmospheric pressure gradients, etc. have not been included in the equations. These terms do not introduce significant additional difficulties from the point of view of the numerical solution and shall not, therefore, be here considered.

The linear long-wave equations are easily derived from (6) and (7) and may be written as:

$$\frac{\partial \eta}{\partial t} + \nabla \vec{Q} = 0 \tag{13}$$

$$\frac{\partial \vec{Q}}{\partial t} + gh \nabla \eta = 0 \tag{14}$$

These lower order relation can be used for manipulating the third-derivative terms as demonstrated by (Long, 1964).

3. Hydrodynamic Model Numerical Solution

3.1. Discretization

The system of partial differential equations (6) and (7) can be discretized by means of an Abbot-type alternating di-

rection implicit finite-differences scheme.

The resulting algorithm is centred both in space and time and is solved by means of a double sweeping technique along both coordinate axes x and y . This technique allows the solution of the implicit equations without having to resort to matrix inversion operations, always cumbersome and time consuming.

This scheme is consistent with the original system of differential equations and it may also be shown to be conditionally stable and convergent (S.-Arcilla and Monsó, 1986). The overall truncation error is now of second order and can be improved to third-order with suitable correction terms added to the difference equations and appropriate centering of the convective and Boussinesq terms (Abbott, 1984). Time centering can be achieved by adequate averaging in time and accumulation of information in intermediate levels, as e.g. in (Abbott, 1973) and (S.-Arcilla and Monsó, 1986). An additional trick to improve centering of derivatives is what is usually known as "side-feeding". With this technique inconsistent approximations are introduced in the fractional (auxiliary) time steps that balance themselves to centered and consistent approximations when viewed over a complete time cycle.

Side-feeding is a device by which we can make use of information produced in the immediately preceding sweep to improve the approximation of cross-derivatives.

The right way of doing it is to reverse the sense of column and row computations so that the most up-to-date information comes from different directions in the individual stages (sweeps). This balances the inconsistency in space-derivative approximations when using values in different time levels. An alternative approach is to use quasi-Newton approximation techniques to achieve second-order discrete schemes compatible with the algorithmic structure.

3.2. Solution algorithm

In the Abbott-Ionescu type of schemes (1968) 4 discretized equations are employed. The first group of 2 equations (continuity and x -momentum) is solved with a double sweep along the x -axis in which p is raised a full Δt timestep while information on η is accumulated in an intermediate time-level. As pointed out in some previous papers η^{n+1} is only an intermediate value of a dependent variable in the fractional step scheme and is not representative of a true water level at time $(n+1/2)\Delta t$. In the second half time-step, η is raised from $t + \Delta t/2$ to $t + \Delta t$, while q is raised a full Δt , using the second group of two equations, continuity and y -momentum, with a double sweeping along the y -axis. The corresponding accumulation information is schematized in fig.2 and the staggered disposition of the problem variables is showed in fig. 3.

Fig. 2: "Clock diagram" representing the accumulation of information in the scheme using an intermediate time-level.

Fig. 3: Staggered spatial disposition of the problem variables (H, p, q) once both horizontal and vertical sweeps have been completed.

The full non-linear version of the scheme, however, requires η , p, q values at every nodal point. This is obtained by means of either consistent 2nd-order interpolation or additional double-sweeps.

One step further is a side-feeding scheme, advancing from time level n to time level n+1 by means of a fourfold division of the time step with the following algorithmic structure:

1. Sweep in y direction, laid down with decreasing x.
2. Sweep in x direction, laid down with decreasing y.
3. Sweep in x direction, laid down with increasing y.
4. Sweep in y direction, laid down with increasing x.

In this scheme side feeding is introduced to improve centering in the cross-derivative terms. These terms remain centered when viewed over a complete timestep, while making extensive use of "falsification" in each of the individual stages.

Fig. 4: "Clock diagram" representing the accumulation of information in the scheme using 3 intermediate time-levels.

In figure 4 we represent the information accumulating properties of this scheme adapted from the one presented in (Abbott, 1988).

Close to the boundaries, application of side-feeding presents essentially the same problems as other alternative computations of convective, cross momentum and Boussinesq terms. Information on all dependent variables η , p, q at the boundaries is needed but not always known. To solve

this problem, estimates of the variables have to be provided. Extrapolation can always be used, but may introduce 1st. order truncation error that can spread all over the domain and even introduce unstable components.

Another source of error present in these schemes is the inappropriate centering of the coefficients in the discretized equations. The difficulty arises when their form is not algorithmically compatible with the employed tri-diagonal al-

gorithmic structures (i.e. they cannot be directly introduced without resorting to iteration).

Furthermore, if one looks for a higher accuracy, it is necessary to add correction terms to obtain third order truncation errors because 2nd order differences introduce an error which is of the same order and type as terms in the momentum equation (Boussinesq terms) describing vertical acceleration.

An order-of magnitude analysis has shown that the third order correction terms corresponding to convective, cross-derivatives and Boussinesq terms are much smaller than other terms.

Apart from the numerical schemes, already presented, we are now implementing an "implicit leap-frog" scheme which is both space and time staggered. Here, from the mass conservation law (4), four discretized equations are obtained. If side feeding is considered as well, 8 discretized equations have to be solved. For the linear 2-D case those 4 equations (excluding side-feeding) are the following:

$$\frac{1}{\Delta t} (\eta_{j,k}^{n+1/2} - \eta_{j,k}^{n-1/2}) + \frac{1}{4\Delta x} (P_{j+1,k}^{n+1} - P_{j-1,k}^{n+1} + P_{j+1,k}^{n-1} - P_{j-1,k}^{n-1}) + \frac{1}{2\Delta y} (q_{j,k+1}^n - q_{j,k-1}^n) = 0 \tag{15}$$

$$\frac{1}{2\Delta t} (P_{j,k}^{n+1} - P_{j,k}^{n-1}) + \frac{gh}{4\Delta x} (\eta_{j+1,k}^{n+1/2} - \eta_{j-1,k}^{n+1/2} + \eta_{j+1,k}^{n-1/2} - \eta_{j-1,k}^{n-1/2}) = 0 \tag{16}$$

$$\frac{1}{\Delta t} (\eta_{j,k}^{n+3/2} - \eta_{j,k}^{n+1/2}) + \frac{1}{2\Delta x} (P_{j+1,k}^{n+1} - P_{j-1,k}^{n+1}) + \frac{1}{4\Delta y} (q_{j,k+1}^{n+2} - q_{j,k-1}^{n+2} + q_{j,k+1}^n - q_{j,k-1}^n) = 0 \tag{17}$$

$$\frac{1}{2\Delta t} (q_{j,k}^{n+2} - q_{j,k}^n) + \frac{gh}{4\Delta y} (\eta_{j,k+1}^{n+3/2} - \eta_{j,k-1}^{n+3/2} + \eta_{j,k+1}^{n+1/2} - \eta_{j,k-1}^{n+1/2}) = 0 \tag{18}$$

In Fig. 5 the clock diagram of this time is shown.

The advantages of this algorithm with respect to classical ADI schemes are:
 1. Symmetric treatment of all variables respect to x and y axes, i.e. total isotropy.

Fig.5: "Clock diagram" of the implicit space - time staggered algorithm

2. Splitted discretized mass equations staggered in space and time.
3. Better time-centering of H, as used in the coefficients.
4. No fractioned step correction on the continuity equation is needed to obtain better performance.
5. Easier implementation of open boundary conditions.

The main disadvantage is that all variables are calculated at different time levels, but this is not a severe limitation.

3.3. Boundary conditions

The number of boundary conditions required by the hyperbolic system presented in the previous section is determined by the number of characteristic lines (in 1-D) or surfaces (in 2-D) defined in the considered area (Daubert and Graffe, 1967). The conditions must also define a well-posed problem and allow the exit of waves generated inside the domain.

In recent literature (Verboom et al., 1983) there have been several references to weakly reflecting boundary conditions developed for the 1-D linear hyperbolic equations. These conditions are based on the Riemann invariants for the 1-D case, but are not a good approximation to the physical problem when waves are either not planar or obliquely incident to the open boundary. The use of weakly reflecting conditions in the aforementioned cases induce a non-physical reflection, even though far from boundary the results may be still acceptable. This explains the satisfactory engineering performances of many existing models, in spite of the limitations of their formulation for boundary conditions.

(A.S.-Arcilla and J.L. Monsó, 1986) presented a new approach to treat open boundaries. This new condition allows a reduction of the degree of spurious reflection which, in turn, means an improved accuracy of the model results. In this paper an improvement to the latter approach is proposed. It is based on a linear superposition of the in- and out-going mass-flux vectors, \vec{Q} and free-surface elevations, η , on the open boundary line. This may be written as:

$$(p, q) \equiv \vec{Q} = \vec{Q}_i + \vec{Q}_s \equiv (p_i + p_s, q_i + q_s) \quad (19)$$

in which

i, s: sub-indexes denoting incident (ingoing) and reflected (out-going) waves respectively.

$$\eta = \eta_i + \eta_s \quad (20)$$

The "in-going" values of the variables are known from the specified boundary conditions, and the three additional equations still required to solve the problem are the mass, x-momentum and y-momentum conservation laws.

3.4. Calibration

The presented numerical models have been first calibrated in linearized versions. The non-linear models have been subsequently tested with solitary and cnoidal waves which are analytical solutions of the differential equations when no frictional stresses, Coriolis forces, etc. are considered. Phase and amplitude errors were likewise studied for these non-linear versions, finding excellent results except for the case in which the wave height was an important part of the water depth (i.e. near wave breaking). A sample result is shown in figure 6.

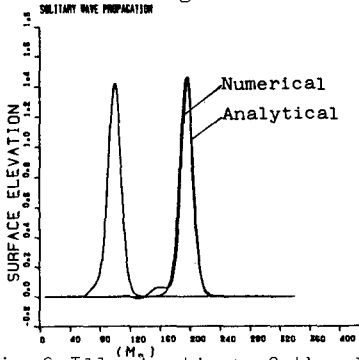

Fig.6: Illustration of the differences obtained with analytical and non-linear equations for 1D wave propagation along a canal of uniform depth.

Once the models had been calibrated with the standard type of boundary conditions, specific tests were designed to ascertain the performance of the open boundary condition described above. One of the most severe test-cases is a square domain with four open sides in which the direction of wave incidence coincides with one of the diagonals. An illustration of the results obtained for this case appears in figure 7. The contour-lines of the disturbed free-surface are, as should be, nearly parallel and perpendicular oriented to the wave propagation direction.

4. Expert System

Artificial Intelligence and Expert Systems (E.S.) are a relatively recent advance in civil engineering. The scope of E.S. projects is usually defined by experts rather than by knowledge engineers. For this reason there is still much work to be done by experts in this field.

With such a system access to high-level expertise can be made readily available to project engineers. This reduces overall costs and eliminates time-delays produced as a result of the expert's prior commitments. From an operational standpoint, immediate access to expert knowledge can significantly reduce non-productive times for labour. Moreover, the capability of the programme to incorporate feed-back information from the engineers can be used to improve its performance.

Fig.7: Contour-lines of the disturbed free surface for a square domain with 4 open sides and oblique wave incidence.

The basic structure of these programmes consists in a knowledge base and an inference mechanism. In the E.S. we are developing, the knowledge representation method is based on production rules. These rules consist in a set of conditions (such as width of harbour entrance, orientation of breakers, depths, etc.) and a set of actions (such as harbour lay-out and bathymetry modifications, etc.). When all conditions in a particular rule are true, the corresponding actions are executed. The conditions are contained in the "IF" part of the rule and the actions in the "THEN" part. Because human experts are not always certain about these rules, conditions and actions may incorporate some associated uncertainty factors. This allows a more realistic representation of the expert's knowledge, based on this degree of confidence in each rule.

The inference mechanism consists of two different methods, viz. forward-chaining and backward-chaining. In both forms the program acquires information either in the form of a question to the engineer or by means of accessing other programs and data bases.

In backward-chaining systems, the program possesses a built-in method to guess an initial solution, i.e. it assumes one particular harbour lay-out configuration. The system then attempts to prove that the assumption is correct, by requiring confirmation of all the prerequisite conditions for this particular lay-out to the expert engineer or by using its own inference capabilities. If the solution is disproved, the program chooses a different possible lay-out configuration and proceeds to test this new solution in the same manner.

In a forward-chaining system, the program has no "a-priori" knowledge of possible harbour lay-outs. It uses the acquired information to evaluate the tree of possibilities, as it progresses through the solution procedure. Information is gathered until the list of possible causes of problems has been narrowed down as much as possible. The reasoning progresses from an initial to a final state, in which the program has reached its goal.

We have selected a backward-chaining strategy, more suitable for our case, because we usually start from an initial lay-out, either imposed by the client or proposed by the expert engineer. This try-and-error or back-tracking technique is usually followed in most design processes. However, it is obvious that the aim of CAD researchers must be the completion of the forward-chaining system applied to harbour lay-out design. This strategy would give an optimal geometric configuration of the harbour with respect to the rules supplied with a minimum of subjective influences.

It is also possible to use a mixed strategy combining both forward-chaining and backward-chaining approaches. The main advantage of this strategy is that the engineer only needs to supply data which are relevant for the problem considered.

In current state-of-art, numerical models are used only in a post-design phase, to evaluate the performance of a final lay-out design, which will be modified only if the obtained results are unacceptable. Because of the time and cost required for a new lay-out analysis, numerical models are used primarily for verification, rather than for feedback or iterative-design improvements.

Our proposed global expert system has the following characteristics:

1. The entire modeling process is carried out on the computer using a combination of interactive and automatized modeling procedures.
2. Expert knowledge is used in the modeling software to increase the level of automatization and to aid the engineer in making better decisions.
3. The engineer is relieved of the need to make rudimentary calculations.
4. The engineer can always ask why the programmed modeling rules pretend to model a particular geometric configuration of the harbour.

The result will be not only a drastic reduction in the time and effort required, but also an improved reliability in the designing process.

5. Engineering Applications

In this section, results from an existing numerical model for wave propagation, based on Boussinesq-type shallow-water equations are presented in the context of harbour lay-out. This model is the basis for the improvements herein proposed.

The first case presented belongs to the wave propagation analysis carried out to design the new lay-out of the Bilbo Harbour in the North Coast of Spain.

The main aim of the study was to improve the hydrodynamic design of the harbour lay-out. The overall plan dimensions were approximately 7 Km. x 5 Km. which required more than 10^5 grid-points in the discretization.

The inputs for the runs were irregular time-series of free-surface elevations generated from a Jonswap spectral density function. This simulated wave record was made to enter the domain from different directions through the open boundary.

Figures 8 and 9 depict the contours of equal variance for two different geometries of the Bilbo Harbour. It is easy to understand now these and similar results may be used to estimate the lay-out design.

Fig.8: Isolines of variance for the wave propagation problem in the new Bilbo Harbour (Superport).

Fig.9: Isolines of variance for the wave propagation problem in the new Bilbo Harbour (Superport).

The second example presented is an application of the system to design the entrance of a harbour in the Catalonia Coast. After some variations in entrance geometry and wave climate conditions, a final optimized configuration was obtained. Figures 10 and 11 show two possible lay-outs.

Fig.10: Equal variance contour-lines and entrance lay-out for the second example presented.

Fig.11: Equal variance contour lines and entrance lay-out for the second example presented.

The last case presented is an application of the system to design the lay-out of a marina at the Canary Islands, Spain. In this example we had to design the width and depth of the canal, including the entrance configuration, so as to obtain a better overall performance from a hydrodynamic standpoint (i.e. to provide shelter) without interfering with the set of operational constraints imposed. Some sample results corresponding to different entrance lay-outs are shown in figures 12 and 13.

6. Conclusions

In this paper, a CAD expert system for harbour lay-out is presented. The system is based in previous experience acquired by the use of hydrodynamic numerical models for wave-current propagation. Some of the obtained results have been presented together with a new, improved numerical scheme.

The most important conclusions are the following:

1. A new ADI scheme has been presented combining the virtues of the leapfrog-scheme with the efficiency of ADI schemes. In this algorithm all the variables are evaluated at different time-levels. This allows a better centering of the discretized mass conservation equations together with a total isotropy of performance.
2. The proposed open boundary condition provides an improvement over former weakly reflecting conditions. This, in turn, means a higher degree of accuracy in the simulations.
3. A new third order scheme, which is now being developed is expected to provide improved results with finite amplitude wind waves in which the wave height is an important part of the water depth. This means a reduction of the number of mesh points, for the same truncation error.
4. The use of a numerical model, based on Boussinesq-type equations, as a module of a global expert system both from technical and economical standpoint will make it possible to obtain an improved design for harbour layouts.

CHAPTER 33

VERTICAL VARIATION OF UNDERTOW IN THE SURF ZONE

ABSTRACT

In order to establish a model of the vertical distribution of the undertow, laboratory experiments were performed on uniform slopes of 1/20 and 1/30. The turbulent velocity in the surf zone including the area close to the bottom was measured by using a two-component laser doppler velocimeter. The distributions of the mean Reynolds stress and the mean eddy viscosity coefficient were calculated. Based on the experimental results, a model to predict the vertical profile of the undertow was presented.

1. INTRODUCTION

The velocity field in the surf zone is of great importance in the coastal engineering problems. In order to predict the sediment transport rate or the wave attenuation rate in the surf zone, it is necessary to estimate the velocity distribution with high accuracy. Especially, the prediction of the velocity near the bottom is necessary for the evaluation of both of the sediment transport rate and the bottom friction factor. In this study, we focus our attention on the evaluation of the undertow in the inner region of the surf zone.

The existence of the undertow was first observed by Bagnold (1940). After that, some researches of the undertow were carried out with laboratory measurements [see e.g. Hansen and Svendsen (1984)]. Recently, Svendsen (1984) presented a model for estimating the vertical distribution of the undertow applying the eddy viscosity model. He used a boundary condition in which the mass transport velocity on the bottom was given by the Stokes wave theory. Tsuchiya et al.(1988) gave the boundary condition at the trough level.

Okayasu et al.(1986) also presented a model which had a slip condition on the bottom. Nadaoka and Hirose (1986) evaluated the diffusion coefficient in the surf zone. They also discussed the vertical distribution of the steady current on the basis of the distribution of the mean vorticity.

However, the above mentioned studies may have a problem in formulating the velocity field near the bottom, and therefore they may not accurately evaluate the velocity distribution near the bottom or the bottom shear stress. From this point of view, Svendsen (1988) theoretically evolved his model taking the bottom boundary layer into account, but the applicability is still unknown. One reason for that is the lack of the velocity data near the bottom.

In the present study, laboratory experiments on constant slopes were performed under various regular wave conditions. The velocity field in the surf zone including the area close to the bottom was measured by a two-component laser doppler velocimeter. The first objective of the present study is to evaluate the distributions of the mean Reynolds stress and the mean eddy viscosity coefficient in the surf zone based on the experimental results. The second objective is to present a model for estimating the vertical distribution of the steady current below the trough level which is valid through the inner region of the surf zone including near the bottom.

2 EXPERIMENT

2.1 Experimental Arrangements

Ten experiments were performed on 1/20 and 1/30 constant slopes of smooth beds for various incident waves. The flume was 23m long and 0.8m wide and had a partition at the center for the sake of keeping the phenomena to be two-dimensional. In Case 5, plastic mirrors were placed on the bottom to prevent reflected laser beams from disturbing the signal. This was proved to be successful in getting velocity data with high S/N (signal to noise) ratio. The still water

Table 1 Experimental condition

10		1.23	6.05	0.0279	-290	spilling

depths in the offshore regions were 40.0cm (39.5cm in Case 5). The experimental condition is listed in Table 1.

In the table, T is the wave period, H_i the wave height in the offshore region of the constant depth, H_0/L_0 the deep-water wave steepness, x_b the wave breaking point, x_p the wave plunging point. The x -axis and z -axis were set to be shoreward and vertically upward, respectively. The origin of the co-ordinates was the shoreline at the still water level.

An arrangement of the measuring points which was rough in the horizontal direction and close in the vertical direction was adopted for the purpose of detailed measurements of the undertow profiles. The measuring points were arranged along 6 or 7 vertical measuring lines in every case except Case 5. The arrangement of Case 5 will be mentioned later. The first measuring line was set on the wave breaking point. The second line was located on the plunging point in case of plunging breakers, or the intermediate point between lines 1 and 3 for spilling breakers. From the third line, the measuring lines were arranged in the inner regions where the surface rollers developed well. The lowest measuring points in each measuring line are 1mm above the bottom in case of 1/20 slope, and for the cases of 1/30 slope they are 2mm above the bottom. The vertical distance of those points were 1-20mm and the highest points are near the mean water levels. For example, the arrangement of Case 1 is shown in Fig.1.

In Case 5, the measuring points were taken only close to the bottom to investigate the detail of the bottom boundary layer in the surf zone. Nine measuring lines were allocated every 40cm of distance from the offshore side of the breaking point to the still water shoreline. The measuring points were arranged 1, 2, 3, 5, 10 and 20mm above the bottom along each line.

Fig.1 Arrangement of the measuring points for Case 1.

2.2 Data Processing and Analysis

A two-component laser doppler velocimeter was used to measure the time history of two-dimensional velocity vector lying on the xz -plane. The velocity data were sampled every 10ms and were converted into digital data over 100 wave periods. The data of the water surface elevation over the measuring point were also taken simultaneously by using a capacitance-type wave gage.

The ensemble mean (equi-phase-mean) value of velocity which is expressed by u in x -direction or w in z -direction was calculated as the average of the velocity at the same phase of every wave. The steady current was calculated from those ensemble mean values. The turbulence component denoted by u' or w' was determined as the deviation from the ensemble mean value. The Reynolds stress was calculated from the turbulence. The mean Reynolds stress $-\rho\overline{u'w'}$ was obtained by averaging the Reynolds stress over one wave period, where ρ is the water density. From the steady current and the mean Reynolds stress, the mean eddy viscosity coefficient ν_t was calculated by using the eddy viscosity model.

2.3 Experimental Results

Figure 2 gives an example of the steady current distribution for Case 2. It can be seen that the undertow profile in the inner region is significantly different from that around the breaking point. Figure 3 is the steady current of Case 5. In the inner region the velocity at the elevation of 1mm above the bottom indicates large value in the offshore direction, while it still directs onshore at the plunging point. This is because the oscillatory bottom boundary layer in the inner region does not develop well due to the agitation of the turbulence from the upper layer. The

Fig.2 Distribution of the steady currents for Case 2.

Fig.3 Distribution of the steady currents for Case 5.

Fig.4 Distributions of the mean Reynolds stress for Cases 2 and 8.

influence by the bottom to the steady current can be seen up to 3mm above the bottom there.

Figure 4 shows the distributions of the mean Reynolds stress of Cases 2 and 8. The distributions of the mean eddy viscosity coefficient of those cases are given in Fig.5. In the figures, it can be seen that both of them decrease linearly from the trough level to the bottom in the inner region. On the bottom, the value of the mean eddy viscosity coefficient is very small compared with that at the trough level. This should corresponds to the fact that the turbulence produced by the large vortex on the front face of the wave crests is far larger than that generated near the bottom. But with respect to the mean Reynolds stress, it is observed that the offshoreward directed shear stress is too large to be neglected. Some researches were done with the assumption that the mean eddy viscosity is independent of the vertical coordinate [e.g. Svendsen and Hansen (1988) or Tsuchiya et al.(1988)], but the result of this study is not consistent with that assumption.

Fig.5 Distributions of the mean eddy viscosity coefficient for Cases 2 and 8.

3 MODELING OF UNDERTOW

3.1 On-offshore Variation of Vertically Averaged Undertow

It can be considered that the mass flux by the breaking waves in the inner region consists of two components, the mass flux by the wave motion and that by the large vortex formed just in front of the wave crest. That means, the vertically averaged value of the undertow can be separated into two parts which are the contribution U_S from the wave component and U_r from the onshore mass flux by the large vortex [Okayasu et al.(1986)].

U_S can be calculated from the wave profile by using the stream function method of Dean (1965). As the calculation by the stream function method is done with the assumption of no shear stress on the bottom, the velocity very close to the bottom should not agree with the actual velocity. However, it would not be a problem when we discuss about the vertically averaged on-offshore steady current because the oscillatory bottom boundary layer by the wave motion is much thinner than that of the steady current.

On the other hand, U_r in the inner region can be estimated by the square of the local wave height H as Svendsen (1984) did, and it does not depend on the incident wave condition. The onshore mass flux by the large vortex can be expressed as

$$M_r = \frac{AH^2}{T}, \quad (1)$$

where A is a constant. And U_r can be obtained by dividing M_r by the trough level d_t as

$$U_r = - \frac{AH^2}{d_t T}. \quad (2)$$

The calculated value U_c of the vertically averaged undertow in the inner region is

$$U_c = U_S + U_r = U_S - \frac{AH^2}{d_t T}. \quad (3)$$

In the equation, we used the value

$$A = 2.3, \quad (4)$$

in all cases based on the laboratory data. In order to decide A , the value

$$A' = - (U_m - U_S) \frac{d_t T}{H^2}, \quad (5)$$

was calculated for each measuring line except Case 5, where U_m is the vertically averaged value of the measured undertow. Next we averaged A' of all measuring lines in the inner region, and took the average again for all cases. The influence of the bottom slope to the constant A could not be

revealed by the experiments.

The comparison between the calculated value U_c and measured value U_m for Case 2 is shown in Fig.6. Here we set A equal to be 0 from the breaking point to the plunging point then changed the value linearly in the distance to the inner region. The value A was 2.3 in the inner region.

Fig.6 Comparison between the measured and the calculated value of the vertically averaged undertow for Case 2.

3.2 Modeling of Vertical Distributions of Mean Reynolds Stress and Mean Eddy Viscosity

Based on the experimental results mentioned in Section 2.3, the vertical distributions of the mean Reynolds stress and the mean eddy viscosity coefficient can be assumed as linear functions of the vertical elevation z . This assumption is different from that used by Svendsen and Hansen (1988) or Tsuchiya et al.(1988). Figure 7 shows this

Fig.7 Assumed distributions of the mean Reynolds stress and the mean eddy viscosity coefficient.

model. The constants in the model were investigated as follows.

First, the coefficients of the linear functions for the measuring lines 4 and 5 were obtained for all cases by using the regression analysis. Then the coefficients were non-dimensionalized by using the water density ρ , the celerity c and the trough depth d_t as the representative values. At last, the averages of the measuring lines 4 and 5 were taken. Using these parameters, the linear functions was expressed as

$$-\rho \overline{u^T w^T} = \alpha_1 \rho \frac{c^2}{d_t} z' + \beta_1 \rho c^2, \quad (6)$$

$$v_t = \alpha_2 c z' + \beta_2 c d_t, \quad (7)$$

where α_1 , β_1 , α_2 and β_2 are dimensionless parameters and z' is the vertical elevation from the bottom. The wave celerity is expressed as

$$c = \sqrt{g (d_t + H)}, \quad (8)$$

on the basis of the solitary wave theory, where g is the gravity acceleration. Table 2 is the list of the dimensionless parameters.

Table 2 Dimensionless parameters for the distribution of $-\rho \overline{u^T w^T}$ and v_t

Case	slope	α_1	β_1	α_2	β_2	γ_2
1		0.0024	-0.00058	0.015	-0.00042	0.015
2		0.0027	-0.00062	0.015	-0.0015	0.014
3	1/20	0.0020	-0.00026	0.0098	0.0013	0.011
4		0.0022	-0.00016	0.015	0.0015	0.016
Ave. of 1/20		0.0023	-0.00041	0.014	0.00022	0.014
6		0.0018	-0.00036	0.010	0.000066	0.010
7		0.0015	-0.00024	0.017	-0.00052	0.016
8	1/30	0.0019	-0.00036	0.011	-0.00043	0.010
9		0.0013	-0.00024	0.0091	-0.00010	0.0081
10		0.0011	-0.00016	0.0046	0.00042	0.0050
Ave. of 1/30		0.0015	-0.00027	0.010	-0.00011	0.0099

In the table, the parameter β_2 is the dimensionless value of v_t on the bottom ($z' = 0$) and γ_2 is the value at the trough level ($z' = d_t$). We can find that β_2 is far smaller than γ_2 and it is consistent with the experimental result. Therefore, it should be possible to take $v_t = 0$ on the bottom. Equation (7) can be approximated as

$$v_t = \alpha_2 c z'. \quad (9)$$

In each bottom slope, the variance of the parameters is so small that the parameters can be regarded as constants. Hence the averaged values are taken for each slope.

Considering the influence of the bottom slope $\tan\beta$, we simply express the parameters as

$$\begin{aligned}\alpha_1 &= 0.046 \tan\beta , \\ \beta_1 &= -0.008 \tan\beta , \\ \alpha_2 &= 0.30 \tan\beta .\end{aligned}\tag{10}$$

Substituting Eq.(10) into Eqs.(6) and (9), we obtain the equations for the distributions of the mean Reynolds stress and the mean eddy viscosity coefficient as

$$-\rho \overline{u'w'} = 0.046 \tan\beta \rho \frac{c^2}{d_t} z' - 0.008 \tan\beta \rho c^2 ,\tag{11}$$

$$v_t = 0.30 \tan\beta c z' .\tag{12}$$

3.4 Vertical Variation of Undertow

By using the eddy viscosity model, the relation between the mean shear stress $\bar{\tau}$ acting on the horizontal plane and the steady current U in x -direction is expressed as

$$\bar{\tau} = \rho v_t \frac{\partial U}{\partial z} .\tag{13}$$

Transforming $\bar{\tau}$ to $-\rho \overline{u'w'}$ and considering Eq.(6), we obtain the equation

$$\frac{1}{\rho} \frac{\partial \bar{\tau}}{\partial z} = \frac{\partial}{\partial z} \left\{ v_t \frac{\partial U}{\partial z} \right\} \equiv C_1 ,\tag{14}$$

where C_1 is a constant. And from the Eq.(9), v_t can be expressed as

$$v_t = C_2 z' ,\tag{15}$$

where C_2 is also a constant. If using z' instead of z , we get

$$\frac{\partial}{\partial z'} \left\{ z' \frac{\partial U}{\partial z'} \right\} = \frac{C_1}{C_2} ,\tag{16}$$

from Eq.(14). This equation can be integrated by using integral constants C_3 and C_4 as

$$U = C_3 \ln z' + C_4 + \frac{C_1}{C_2} z' .\tag{17}$$

It can be considered that the third term of the right hand side of Eq.(17) directly expresses the "shear effect" termed by Nadaoka and Hirose (1986). C_1 and C_2 can be decided as

$$C_1 = 0.046 \tan\beta \frac{c^2}{d_t} ,\tag{18}$$

$$C_2 = 0.30 \tan\beta c ,\tag{19}$$

from Eqs.(11) and (12). The boundary condition at the trough level is given by using Eq.(13) as

$$\left. \frac{\partial U}{\partial z'} \right|_{d_t} = \frac{1}{\rho} \left. \frac{\bar{\tau}}{v_t} \right|_{d_t} = \frac{0.038 \tan \beta c^2}{C_2 d_t} . \quad (20)$$

Substituting Eq.(20) into the first derivation of Eq.(17) which is

$$\frac{\partial U}{\partial z'} = \frac{C_3}{z'} + \frac{C_1}{C_2} , \quad (21)$$

we obtain

$$C_3 = \left[\frac{0.038 \tan \beta c^2}{C_2 d_t} - \frac{C_1}{C_2} \right] d_t = -0.027c . \quad (22)$$

Furthermore, By using the relation

$$\begin{aligned} U_c &= \frac{1}{d_t} \int_0^{d_t} U dz' \\ &= C_3 (\ln d_t - 1) + C_4 + \frac{1}{2} \frac{C_1}{C_2} d_t , \end{aligned} \quad (23)$$

the constant C_4 is given as

$$C_4 = U_c + C_3 (1 - \ln d_t) - \frac{1}{2} \frac{C_1}{C_2} d_t . \quad (24)$$

From the equations above, the vertical distribution of the undertow can be obtained as

$$\begin{aligned} U &= U_c + C_3 \left(\ln \frac{z'}{d_t} + 1 \right) + \frac{C_1}{C_2} \left(z' - \frac{d_t}{2} \right) \\ &= -0.027c \ln \frac{z'}{d_t} + 0.15c \frac{z'}{d_t} - 0.10c + U_c . \end{aligned} \quad (25)$$

In the equation, the bottom steepness $\tan \beta$ does not appear.

4. COMPARISONS WITH THE EXPERIMENTAL RESULTS

Using Eq.(25), we can evaluate the undertow profile from the time history of the wave profile at that point. Figure 8 gives the comparisons between the measured and the calculated undertow profiles for the measuring lines 3 and 5 of 1/20 slope by using Eq.(25). In the figure, a dimensionless value which is obtained by dividing U by the absolute value of U_c is taken for the horizontal coordinate, and the vertical coordinate is z'/d_t . The positions of the measuring lines are indicated by x/x_b . The comparisons for the 1/30 slope are also shown in Fig.9.

The nondimensional parameters which determine the each constant in Eq.(25) are invariant through the all cases and

Fig.8 Comparisons between the measured and the calculated undertow profiles for the 1/20 slope.

Fig.9 Comparisons between the measured and the calculated undertow profiles for the 1/30 slope.

the agreement between the measured and calculated values is good. However, in general the gradient of the calculated values are a little smaller than the measured values in the upper regions, that means the further investigation for estimating C_1 and C_2 in Eq.(25) is required.

Figure 10 shows the comparisons when we apply Eq.(25) to Case 5 of the 1/20 slope. The agreement is well especially in the area close to the bottom. It can be said that the model is usable for evaluating the steady current distribution close to the bottom in various conditions.

Fig.10 Comparisons between the measured and the calculated undertow profiles for Case 5.

5. CONCLUDING REMARKS

The velocity distribution in the surf zone on 1/20 and 1/30 constant slopes was measured in detail by using a two-component laser doppler velocimeter. The distributions of the steady current, the mean Reynolds stress and the mean eddy viscosity coefficient were evaluated. A model was proposed to estimate the vertical distribution of the undertow in the inner region, especially close to the bottom.

The conclusions are as follows.

(1) The mean Reynolds stress and the mean eddy viscosity coefficient in the inner region can be regarded as linear functions of the vertical elevation. The offshore directed mean shear stress on the bottom is so large that it can not be neglected. The nondimensional parameters which express the linear distribution can be expressed in terms of the bottom slope.

(2) The vertically averaged on-offshore steady current can be evaluated from the sum of two components: the first component is resulted from the wave component and the second one from the large vortex formed just in front of the wave crest. The second component can be evaluated by the square of the local wave height.

(3) The vertical distribution of the undertow in the inner region of the surf zone can be estimated by using Eq.(25). The calculated undertow profiles agree well with the measured values near the bottom. However, further investigations are required for the accurate evaluation around the trough level.

CHAPTER 34

Spectral Wave Attenuation by Bottom Friction: Theory

Ole Secher Madsen¹, Ying-Keung Poon², and Hans C. Graber³

ABSTRACT

Based on the linearized form of the boundary layer equations and a simple eddy viscosity formulation of shear stress, the turbulent bottom boundary layer flow is obtained for a wave motion specified by its directional spectrum. Closure is obtained by requiring the solution to reduce, in the limit, to that of a simple harmonic wave. The resulting dissipation is obtained in spectral form with a single friction factor determined from knowledge of the bottom roughness and an equivalent monochromatic wave having the same root-mean-square near-bottom orbital velocity and excursion amplitude as the specified wave spectrum. The total spectral dissipation rate is obtained by integration and compared with the average dissipation obtained from a model considering the statistics of individual waves defined by their maximum orbital velocity and zero-crossing period. The agreement between the two different evaluations of total spectral dissipation supports the validity of the spectral dissipation model.

INTRODUCTION

As waves propagate into water of finite depth the presence of a bottom manifests itself in various ways, e.g., causing shoaling, depth-refraction, and dissipation of energy. In the present context of wave attenuation by bottom friction the most important manifestation of the bottom is the establishment of a bottom boundary layer in the immediate vicinity of the bottom. Within this wave boundary layer, of thickness a few cm, the flow is strongly sheared, generally turbulent, and associated with significant dissipation of energy.

Several models for turbulent wave boundary layer flows and associated energy dissipation have been developed, e.g., Putnam and Johnson (1949), Kajiura (1964, 1968), and Jonsson (1966), to mention a few of the earliest contributions. According to these (and later contributions) the

attenuation of periodic waves in constant but finite water depth, h , may be expressed formally through the conservation of wave energy equation

$$\frac{\partial E}{\partial t} + \frac{\partial E_f}{\partial x} = -E_d \quad (1)$$

where, according to linear wave theory,

$$\begin{aligned} E &= \frac{1}{2} \rho g a^2 \\ E_f &= c_g E = \frac{1}{2} \left[1 + \frac{2kh}{\sinh 2kh} \right] \frac{\omega}{k} E \\ \omega^2 &= kg \tanh kh \end{aligned} \quad (2)$$

and the average rate of energy dissipation by bottom friction is obtained from

$$E_d = \langle \tau_b u_{\infty} \rangle \simeq \frac{1}{4} \rho f_w u_{br} u_b^2 \quad (3)$$

in which f_w is the wave friction factor (Jonsson, 1966), $u_b = (a\omega/\sinh kh)$ is the near-bottom maximum orbital velocity, and $u_{br} = (8/3\pi)u_b$. Use of Eqs. (1) through (3) allows evaluation of the wave attenuation due to bottom friction to be performed from knowledge of the periodic wave characteristics--amplitude $a = H/2$ and radian frequency $\omega = 2\pi/T$ --and the bottom roughness. For practical applications, however, real waves are not periodic and the question arises which wave amplitude (wave height) and period to choose to represent the random wave field.

An alternative approach was taken by Hasselmann and Collins (1968) who evaluated the average rate of dissipation from $\langle \tau_b u_{\infty} \rangle$ treating $\tau_b = \frac{1}{2} \rho f_w |u_{\infty}| u_{\infty}$ and u_{∞} as random variables defined by the directional spectrum of u_{∞} , the near-bottom orbital velocity. A simplified version of their analysis, corresponding to the use of Eqs. (1) through (3) for each wave component with u_{br} being the orbital velocity having the same root-mean-square value as the specified spectrum, was later proposed and used by Collins (1972) to evaluate the spectral attenuation of waves due to bottom friction. While overcoming the problem of which equivalent periodic wave to choose to represent the wave spectrum, the Hasselmann-Collins approach does not provide information on how the friction factor is related to bottom roughness. Thus the friction factor, f_w , becomes a parameter to be fitted by comparison of model predictions and observations, e.g., Hsiao and Shemdin (1978).

To overcome the problem associated with available models for the prediction of attenuation of waves by bottom friction, we start from the linear equation governing the bottom boundary layer flow. A simple, time-invariant eddy viscosity formulation is used to express the turbulent shear stress and a solution for the boundary layer flow is obtained for a wave motion specified by its directional spectrum. The problem is closed by requiring the spectral representation of the bottom shear stress to reduce the known solution, e.g., Grant and Madsen (1979, 1986), in the limit of a single periodic wave. In this manner theoretical justification is obtained for the application of Eqs. (1) through (3) for each spectral wave component with u_{br}

as specified by Collins (1972). However, in contrast to Collins's study the present analysis also results in a relationship for the friction factor, f_w , in terms of spectral wave characteristics--represented by an equivalent periodic wave having the same root-mean-square near-bottom orbital velocity and excursion amplitude--and the bottom roughness.

Integration of the spectral wave dissipation model over all frequencies produces an expression for the total average dissipation rate associated with a wave motion specified by its frequency spectrum. This estimate of the average dissipation rate is compared with that obtained from a model which considers the joint probability of near-bottom orbital velocity and zero-crossing period derived from the near-bottom orbital velocity spectrum following Longuet-Higgins (1983). Besides resulting in comparable estimates of total average dissipation, thereby supporting the validity of the spectral dissipation model, the total dissipation rate is expressed in terms of representative surface wave characteristics, root-mean-square wave height and significant period, which greatly facilitates the approximate computation of wave attenuation by bottom friction.

SPECTRAL DISSIPATION MODEL

Governing Equation

We start by adopting the linearized boundary layer approximation for the flow above a horizontal bottom located at $z = 0$, i.e.,

$$\frac{\partial \vec{u}}{\partial t} = -\nabla(p/\rho) + \frac{\partial(\vec{\tau}/\rho)}{\partial z} \quad (4)$$

in which $\vec{u} = (u, v)$ and $\vec{\tau}$ are the velocity and shear stress, respectively, ∇ is the horizontal (x, y) gradient operator, and ρ is the fluid density. Realizing that the shear stress vanishes while the velocity approaches its free stream value as $z \rightarrow \infty$, we have

$$\frac{\partial \vec{u}_\infty}{\partial t} = -\nabla(p/\rho) \quad (5)$$

For small values of z , i.e., as the solid boundary is approached, the no-slip condition requires the velocity to approach zero. Thus, we obtain as $z \rightarrow 0$

$$\frac{\partial(\vec{\tau}/\rho)}{\partial z} = -\frac{\partial \vec{u}_\infty}{\partial t} = \nabla(p/\rho) \quad (6)$$

which, by integration from $z = "0"$, where $\vec{\tau} = \vec{\tau}_b$, to $z = 0^+$ yields

$$\vec{\tau} = \vec{\tau}_b - \int_{"0"}^{0^+} \rho \frac{\partial \vec{u}_\infty}{\partial t} dz \simeq \vec{\tau}_b \quad (7)$$

i.e., a constant shear stress equal to the boundary shear stress within a region close to the solid boundary

($z \leq 0^+$). In this context it should be pointed out that "constant" refers to the spatial not the temporal variation, since τ_b clearly will vary with time.

Thus in a region very close to the solid bottom the "law of the wall" is valid. In analogy with steady turbulent flows over a rough wall we therefore expect a logarithmic velocity profile for $z \leq 0^+$. This requirement is met if we express the shear stress through the concept of a vertical turbulent eddy viscosity, ν_t , which varies linearly with distance from the bottom, i.e., if we take

$$\tau/\rho = \nu_t \frac{\partial \vec{u}}{\partial z} = \kappa u_{*r} z \frac{\partial \vec{u}}{\partial z} \quad (8)$$

Strictly speaking we should carry the dynamic analogy with steady turbulent flows further by requiring the friction velocity u_{*r} to be $\sqrt{(\tau_b/\rho)}$ with τ_b denoting the time-varying magnitude of the bottom shear stress. However, Trowbridge and Madsen (1984a, b) considered this complication, in the context of periodic wave boundary layers, and concluded that a time-invariant eddy viscosity suffices so long as the boundary layer analysis is limited to first order in wave steepness as is the case here. For this reason we adopt the expression for the turbulent shear stress given by Eq. (8) with u_{*r} denoting a time-invariant representative friction velocity.

Incorporating Eqs. (5) and (8) in (4) and realizing that $u_\infty \neq u_\infty(z)$ we obtain

$$\frac{\partial(\vec{u} - \vec{u}_\infty)}{\partial t} = \frac{\partial}{\partial z} \left[\kappa u_{*r} z \frac{\partial(\vec{u} - \vec{u}_\infty)}{\partial z} \right] \quad (9)$$

governing the turbulent flow within the bottom boundary layer.

Solution

To solve the governing equation we specify the free stream velocity as that associated with a directional wave spectrum, i.e.,

$$\vec{u}_\infty = \sum_n \sum_m u_{b,nm} (\cos \theta_m, \sin \theta_m) e^{i\omega_n t} \quad (10)$$

in which n and m denote summation over frequencies and directions, respectively. With this representation of u_∞ the velocity amplitudes $u_{b,nm}$ are related to the near-bottom orbital velocity spectrum and to the directional surface amplitude spectrum through

$$u_{b,nm} = \sqrt{2S_{u_b}(\omega_n, \theta_m) d\theta d\omega} = \frac{\omega_n}{\sinh k_h h} \sqrt{2S_\eta(\omega_n, \theta_m) d\theta d\omega} \quad (11)$$

in which ω_n and k_n are related through the linear dispersion relationship, Eq. (2).

The linearity of Eq. (9) combined with the assumed time-invariant representative friction velocity suggests a solution of the form

$$\vec{u} = \sum_n \sum_m u_{nm} (\cos \theta_m, \sin \theta_m) e^{i\omega_n t} \quad (12)$$

in which $u_{nm} = u_{nm}(z)$ represents the complex velocity component amplitudes and only the real part of Eq. (12) constitutes the solution sought.

Introducing Eqs. (10) and (12) in (9) we obtain the equation for each velocity component

$$\frac{d}{d\zeta_n} \left[\zeta_n \frac{d\tilde{u}_{nm}}{d\zeta_n} \right] - i\tilde{u}_{nm} = 0 \quad (13)$$

in which

$$\begin{aligned} \tilde{u}_{nm} &= u_{nm} - u_{b,nm} \\ \zeta_n &= z\omega_n / (\kappa u_{*r}) \end{aligned} \quad (14)$$

The boundary conditions to be satisfied by each component are

$$\begin{aligned} \tilde{u}_{nm} &\rightarrow 0 & \text{as} & \zeta_n \rightarrow \infty \\ \tilde{u}_{nm} &= -u_{b,nm} & \text{for} & \zeta_n = \zeta_{n0} = z_0\omega_n / (\kappa u_{*r}) \end{aligned} \quad (15)$$

where, once again, we have drawn upon the analogy with steady turbulent flows over a rough boundary by requiring the no-slip condition to be satisfied at $z = z_0 = k_b/30$, where k_b is the equivalent Nikuradse sand grain roughness of the bottom.

The solution to Eq. (13) subject to the boundary conditions stated in Eq. (15) may be written in terms of Kelvin functions of zeroth order (e.g., Hildebrand, 1976)

$$\tilde{u}_{nm} = - \frac{\text{ker}2\sqrt{\zeta_n} + i \text{kei}2\sqrt{\zeta_n}}{\text{ker}2\sqrt{\zeta_{n0}} + i \text{kei}2\sqrt{\zeta_{n0}}} u_{b,nm} \quad (16)$$

Invoking the limiting form of Kelvin functions for small values of their arguments (Abramowitz and Stegun, 1972, Ch. 9) we obtain from Eqs. (12), (14), and (16)

$$|\vec{u}_{nm}| = \frac{u_{b,nm}}{\left[\left[\ln \frac{\kappa u_{*r}}{z_0 \omega_n} - 1.15 \right]^2 + \left[\frac{\pi}{2} \right]^2 \right]^{1/2}} \ln \frac{z}{z_0} \cos(\omega_n t + \phi_n) \quad (17)$$

where

$$\tan \phi_n = \frac{\pi/2}{\ln \frac{\kappa u_{*r}}{z_0 \omega_n} - 1.15} \quad (18)$$

valid for small z .

Closure

While a solution for the turbulent flow in the wave boundary layer has been obtained, this solution involves the representative friction velocity u_{*r} which is yet to be

specified. From the expression for the bottom shear stress, Eq. (8), we obtain with the velocity solution given by Eq. (17)

$$\begin{aligned} \frac{1}{\rho} \tau_{b, nm} &= \lim_{z \rightarrow 0} \left[\kappa u_{*r} z \frac{\partial u_{nm}}{\partial z} \right] \\ &= \frac{\kappa u_{*r}}{\left[\left[\ln \frac{\kappa u_{*r}}{z_0 \omega_n} - 1.15 \right]^2 + \left[\frac{\pi}{2} \right]^2 \right]^{1/2}} u_{b, nm} \end{aligned} \quad (19)$$

Now, in deriving the asymptotic form of u_{nm} as given by Eq. (17) it was assumed that $\zeta_{n0} = z_0 \omega_n / (\kappa u_{*r}) \ll 1$. The proportionality factor between the bottom stress component amplitude, $\tau_{b, nm} / \rho$, and the orbital velocity component amplitude, $u_{b, nm}$, given by Eq. (19) is therefore dominated by the first term in the denominator, which in turn is a weak function of ω_n . We may therefore replace ω_n in Eq. (19) by a constant representative radian frequency, ω_r , and consider the ratio of bottom shear stress and orbital velocity amplitudes to be constant. With these approximations the bottom shear stress spectrum is given in terms of the near-bottom orbital velocity spectrum by

$$S_{\tau_b}(\omega, \theta) = \left[\frac{\rho \kappa u_{*r}}{\ln \frac{\kappa u_{*r}}{z_0 \omega_r} - 1.15} \right]^2 S_{u_b}(\omega, \theta) \quad (20)$$

Integration of Eq. (20) over all frequencies and directions and denoting

$$\begin{aligned} (\tau_{br} / \rho)^2 &= 2 \iint S_{\tau_b / \rho}(\omega, \theta) d\omega d\theta \\ u_{br}^2 &= 2 \iint S_{u_b}(\omega, \theta) d\omega d\theta \end{aligned} \quad (21)$$

we obtain the following relationship

$$\tau_{br} = \frac{\rho \kappa u_{*r}}{\ln \frac{\kappa u_{*r}}{z_0 \omega_r} - 1.15} u_{br} \quad (22)$$

which, given the approximation made in the present analysis, is identical to the result obtained for a periodic wave motion (Grant and Madsen, 1986) when we take

$$u_{*r} = \sqrt{\tau_{br} / \rho} = \sqrt{f_{wr} / 2} u_{br} \quad (23)$$

In fact, Eq. (23) may be introduced in Eq. (22) to obtain an equation for the wave friction factor similar to that originally proposed by Jonsson (1966)

$$\frac{1}{4\sqrt{f_{wr}}} + \log_{10} \frac{1}{4\sqrt{f_{wr}}} = \log_{10} \frac{A_{br}}{k_b} - 0.17 \quad (24)$$

with $k_b = 30z_0$ denoting the equivalent bottom roughness and

$$A_{br}^2 = \left[\frac{u_{br}}{u_r} \right]^2 = 2 \iint \omega^{-2} S_{u_b}(\omega, \theta) d\omega d\theta \quad (25)$$

denoting the near-bottom orbital excursion amplitude of an equivalent periodic wave having the same root-mean-square near-bottom orbital velocity and excursion amplitude as the specified directional wave spectrum. While Eq. (24) is limited to small relative roughness, i.e., large values of A_{br}/k_b , the general formula given by Grant and Madsen (1979) may be used for large relative roughness values.

Spectral Dissipation and Wave Attenuation

Following Kajiura (1968) the average rate of dissipation of wave energy in the bottom boundary layer is given by Eq. (3), $\langle \tau_b u_\infty \rangle$. Expressed in terms of the spectral components of τ_b , Eq. (19), and u_∞ , Eq. (10), including random phase consideration for components of the same frequency, results in

$$\begin{aligned} E_{d,nm} &= \langle \tau_{b,nm} u_{\infty,nm} \rangle = \frac{1}{2} f_{wr} \rho u_{br} u_{b,nm}^2 \langle \cos(\omega_n t + \phi_n) \cos(\omega_n t) \rangle \\ &= \frac{1}{4} f_{wr} \rho u_{br} u_{b,nm}^2 \end{aligned} \quad (26)$$

in which the phase difference between bottom shear stress and free stream velocity--amounting to a $\cos \phi_n$ factor--is neglected to be consistent with previous approximations.

Rewriting the dissipation rate given by Eq. (26) by making use of Eq. (11), we may formally express the conservation of wave energy equation in spectral terms as

$$\begin{aligned} \frac{D(S_\eta(\omega, \theta))}{Dt} &= - \frac{1}{\rho g} E_d(\omega, \theta) = - \frac{1}{2g} f_{wr} u_{br} S_{u_b}(\omega, \theta) \\ &= - \frac{1}{2g} f_{wr} u_{br} \left[\frac{\omega}{\sinh kh} \right]^2 S_\eta(\omega, \theta) \end{aligned} \quad (27)$$

with u_{br} given by Eq. (21) and f_{wr} obtained from knowledge of the equivalent Nikuradse sand grain roughness of the bottom and an equivalent periodic wave having the same root-mean-square orbital velocity and excursion amplitude as the specified directional wave spectrum.

EVALUATION OF TOTAL DISSIPATION

Spectral Model

From the model of spectral dissipation derived in the preceding section we may obtain the average rate of dissipation of energy for the entire wave field by integration of $E_d(\omega, \theta)$, given by Eq. (27), over frequency and direction. Performing this integration and recalling the definition of u_{br} , Eq. (21), the total average dissipation rate may be expressed as

$$E_{d1} = \iint E_d(\omega, \theta) d\omega d\theta = \frac{1}{4} \rho f_{wr} u_{br}^3 \quad (28)$$

While quite simple in appearance, the evaluation of Eq. (21) is somewhat cumbersome since it requires evaluation of quantities that depend on spectral characteristics of the near bottom orbital motion. It would be far simpler if the total average dissipation rate were expressed in terms of wave characteristics derived from the surface amplitude spectrum. We therefore define a characteristic periodic wave with the same root-mean-square amplitude as the wave motion specified by its directional spectrum, i.e.,

$$a_c^2 = 2 \iint S_\eta(\omega, \theta) d\omega d\theta \quad (29)$$

and a period defined by

$$\omega_c = \frac{2\pi}{T_c} = \frac{m_1}{m_0} \quad (30)$$

where m_j denotes the j 'th spectral moment

$$m_j = \iint \omega^j S_\eta(\omega, \theta) d\omega d\theta \quad (31)$$

Denoting the near-bottom velocity associated with this characteristic wave by u_{bc} we have

$$u_{bc} = \frac{a_c \omega_c}{\sinh k_c h} = A_{bc} \omega_c \quad (32)$$

where $k_c = 2\pi/L_c$ is the wave number corresponding to the characteristic wave period, i.e.,

$$\omega_c^2 = k_c g \tanh k_c h \quad (33)$$

Introducing the characteristic wave parameters in the expression for the energy dissipation, Eq. (28), we obtain

$$E_{d1} = \left\{ \frac{f_{wr}}{f_{wc}} \left[\frac{u_{br}}{u_{bc}} \right]^3 \right\} \frac{1}{4} \rho f_{wc} u_{bc}^3 = C_1 E_{dc} \quad (34)$$

where E_{dc} is the average rate of dissipation predicted for the characteristic equivalent periodic wave defined by Eqs. (29) and (30).

Values of C_1 have been computed for JONSWAP spectra with different peak-enhancement values ($\gamma = 1, 3.3, 7$) in different water depths, defined by h/L_c , for a range of different relative bottom roughness, A_{bc}/k_b . The results, shown in Figure 1 as dashed curves, indicate that the value of C_1 depends on spectral peakedness and relative water depth with C_1 increasing as the spectrum becomes broader ($\gamma = 1$) and as the relative depth increases. This behavior reflects the increased importance of the low-frequency part of the surface amplitude spectrum in determining the near-bottom orbital velocity characteristics. Within the range of relative bottom roughness tested, $1 \leq A_{bc}/k_b \leq 1000$, the resulting value of C_1 was found to be essentially independent of this parameter.

Figure 1. Variation of constants C_1 , Eq. (34), and C_2 Eq. (42), for the evaluation of total bottom dissipation for a random wave field with relative water depth h/L_c and spectral peakedness γ .

Individual Wave Model

Longuet-Higgins (1983) derived the joint probability distribution of zero-crossing wave heights and periods for a narrow banded surface spectrum. Replacing the surface amplitude spectrum by the near-bottom orbital velocity spectrum

$$S_{u_b}(\omega) = \left[\frac{\omega}{\sinh kh} \right]^2 S_{\eta}(\omega) \quad (35)$$

the formulae derived by Longuet-Higgins (1983) may be adopted directly to obtain the joint probability of maximum near-bottom orbital velocity and period

$$p(R, \tau) = \frac{2}{\nu\sqrt{\pi}} \left[\frac{R^2}{\tau^2} \right] e^{-R^2[1+(1-1/\tau)^2/\nu^2]} \cdot L(\nu) \quad (36)$$

where

$$R = \frac{u_b}{\sqrt{2M_0}} = \frac{u_b}{u_{br}}$$

$$\tau = \frac{M_1}{2\pi M_0} T = \frac{T}{T_1} \quad (37)$$

denote the normalized maximum orbital velocity, u_b , and period, T , respectively, and

$$1/L(\nu) = [1 + (1 + \nu^2)^{-1/2}]/2$$

$$\nu^2 = \frac{M_0 M_2 - M_1^2}{M_1^2} \quad (38)$$

with M_j denoting the j -th moment of the near-bottom orbital velocity spectrum

$$M_j = \int \omega^j S_{u_b}(\omega) d\omega \quad (39)$$

Assuming each individual wave, defined by u_b and T , to be simple harmonic a friction factor f_w can be calculated for each wave from knowledge of the bottom roughness. Thus, the dissipation of energy associated with a single wave, D , may be written as the product of the average dissipation rate, cf Eq. (26), and the wave period T , i.e.,

$$D = \frac{1}{4} \rho f_w u_b^3 \cdot T = \left[\frac{u_{br}}{u_{bc}} \right]^3 \left[\frac{f_w}{f_{wc}} \left(\frac{u_b}{u_{br}} \right) \frac{3T}{T_1} \right] \frac{1}{4} \rho f_{wc} u_{bc}^3 T_1$$

$$= \left[\frac{u_{br}}{u_{bc}} \right]^2 \left[\frac{f_w}{f_{wc}} R^3 \tau \right] \frac{1}{4} \rho f_{wc} u_{bc}^3 T_1 \quad (40)$$

To obtain the average rate of energy dissipation we sum the contribution of N individual random waves and divide by the time necessary for N waves to pass. This time is NT_2 , where

$$T_2 = 2\pi \left[\frac{M_0}{M_2} \right]^{1/2} \quad (41)$$

is the mean zero-crossing period of the near-bottom waves. Since the number of waves within an area around u_b (or R) and T (or τ) relative to the total number of waves is given by the joint probability density function, Eq. (36), we obtain the average rate of energy dissipation from

$$E_{d2} = \left[\frac{[u_{br}]^3 T_1}{[u_{bc}] T_2} \int_0^\infty \int_0^\infty \frac{f_w R^3 \tau P(R, \tau) dR d\tau}{f_{wc}} \right] E_{dc} = C_2 E_{dc} \quad (42)$$

Again we take the JONSWAP spectrum with $\gamma = 1, 3.3,$ and 7 for the surface amplitude spectrum, transform it into a near-bottom orbital velocity spectrum for different values of h/L_c , and evaluate the constant C_2 in Eq. (42) for a range of relative bottom roughness, $1 \leq A_{bc}/k_b \leq 1000$. Again, the value of C_2 was found insensitive to the value of relative bottom roughness while varying, as shown by the full lines in Figure 1, with relative water depth and spectral peakedness, in much the same manner as found for C_1 .

Over the important range of relative water depths where bottom frictional attenuation is expected to be most pronounced, $h/L_c < 0.25$, the excellent agreement between C_1 and C_2 supports the validity of the simple model for spectral wave dissipation derived here.

SUMMARY AND CONCLUSIONS

Based on a simple formulation of the turbulent flow in a bottom boundary layer a solution is obtained corresponding to a wave motion specified by its near-bottom orbital velocity spectrum. From the solution the spectral wave dissipation is obtained in the form

$$E_d(\omega, \theta) = \frac{1}{2} \rho f_{wr} u_{br} S_{u_b}(\omega, \theta)$$

in which

$$u_{br} = \sqrt{2 \iint S_{u_b}(\omega, \theta) d\omega d\theta}$$

and f_{wr} may be obtained from any of the many available wave friction factor relationships from knowledge of the equivalent Nikuradse roughness of the bottom, k_b , for an equivalent periodic wave of near-bottom orbital velocity u_{br} and radian frequency, ω_r , defined by

$$A_{br} = \sqrt{2 \iint \omega^{-2} S_{u_b}(\omega, \theta) d\omega d\theta} = u_{br}/\omega_r$$

In passing it is noted that the analysis of turbulent wave-current bottom boundary layers, e.g., Grant and Madsen (1979, 1986), may be extended to waves specified by their directional spectrum by an identical procedure to the one employed here for a pure wave bottom boundary layer. The

result of such an analysis, Madsen (in prep.), shows that available theories for wave-current interaction, which assume a periodic wave motion, may be used also to approximate waves specified by their directional spectrum when the spectral wave is represented by the equivalent periodic wave, defined by u_{br} and A_{br} , propagating in the mean wave direction.

In the important range of intermediate to shallow water depths, the total average dissipation rate predicted by the spectral model is shown to agree with the prediction afforded by a model which considers the statistics of individual waves, defined by their near-bottom orbital velocity characteristics. Besides supporting the validity of the spectral dissipation model the formulae and the results presented in Figure 1 for the overall dissipation experienced by random waves may serve as a simple tool for the prediction of wave attenuation by bottom friction. This use of the results presented here is facilitated by the average dissipation rate experienced by random waves being expressed in terms of a characteristic equivalent periodic wave defined in terms of the surface amplitude spectrum. In this context it should be noted that the characteristic equivalent wave is defined with the root-mean-square wave height, not the significant wave height!

The practical limitation of the present results is that they require a priori knowledge of the bottom roughness, k_b . Experimental results directed towards overcoming this limitation are presented in a companion paper by Madsen and Rosengaus (1988).

CHAPTER 35

Subgrid Modelling in Depth Integrated Flows

by

P.A. Madsen, M. Rugbjerg and I.R. Warren

Introduction

Hydrodynamic simulations in coastal engineering studies are still most commonly carried out using two-dimensional vertically integrated mathematical models. As yet, three-dimensional models are too expensive to be put into general use. However, the tendency with 2-D models is to use finer and finer resolution so that it becomes necessary to include approximations to some 3-D phenomena.

It has been shown by many authors that simulations of large scale eddies can be quite realistic in 2-D models (c.f. Abbott et al. 1985).

Basically there exists two different mechanisms of circulation generation. The first one is based on a balance between horizontally and grid-resolved momentum transfers and the bed resistance - i.e. a balance between the convective momentum terms and the bottom shear stress.

The second one is due to momentum transfers that are not resolved at the grid scale but appears instead as horizontally distributed shear stresses.

In many practical situations the circulations will be governed by the first mechanism.

This is the case if the diameter of the circulation and the grid size is much larger than the water depth. In this situation the eddies are friction dominated so that the effect of sub-grid eddy viscosity is limited.

In this case 2-D models are known to produce very realistic results and several comparisons with measurements have been reported in the literature.

However, when $\Delta x \leq h$ then the eddy viscosity becomes the most important parameter determining the flow pattern. In this case the modelling operation must proceed more cau-

tiously and a proper closure of the equations must be made in order to describe the effective shear stresses in the momentum equations.

Effective Stresses

The effective stresses arise in the momentum equations via various filtering processes.

The commonly recognized filtering processes are:

<u>Scale 1:</u> Filter out the random molecular motion	}	→	molecular diffusion
		→	viscosity
<u>Scale 2:</u> Filter out the turbulent motion below a <u>given</u> scale	}	→	turbulent diffusion
		→	eddy-viscosity
<u>Scale 3:</u> Depth averaging to filter out the vertical velocity profile for 2-D models	}	→	dispersion
		→	bed & surface shear stresses
		→	horizontal ("effective") shear stresses

It is generally accepted that the eddy terms due to the processes at scale 1 and 2 are negligible relative to scale 3. The effect of the depth-averaging of the velocity profile was taken care of by Elder (1959) who used a logarithmic profile to derive the following expression for the eddy viscosity,

$$E = K_v \cdot h \cdot u^* \quad , \quad K_v \approx 6$$

where

$$u^* \equiv \sqrt{\frac{\tau}{\rho}} = \sqrt{g} \cdot \frac{u}{C} \quad , \quad C = \text{chezy number}$$

However, field measurements and modelling generally show that Elder's coefficient is several orders of magnitude too small. This is illustrated by table 1 in which calibrated eddy coefficients are compared to Elder's expression for 4 different model applications.

Case	h m	u m/s	u* m/s	Δx m	Δt s	E calib. m ² /s	6·hu* m ² /s
A	8	0.7	0.05	50	30	2-5	2.4
B	20	1.0	0.1	500	300	40-50	12
C	30	0.5	0.03	6000	600	≈500	5.4
D	1000	0.1	0.003	30000	900	>6000	18

Table 1 Comparison between Elder's eddy coefficient and calibrated coefficients.

In most classical texts, the development of the equations for nearly-horizontal flow stop at scale 3. However it turns out that for application to numerical modelling it is necessary to extend the filtering process to scale 4, that of the model resolution:

Scale 4:	}	→	→
Horizontal averaging over the model grid size Δx			

When Δx and h are of the same order of magnitude then the processes at both scales 3 and 4 must be considered.

Many modellers attempt to account for the processes at scale 4 by increasing the coefficient, K_v , in Elder's formula, $K_v hu^*$, but this is a mistake.

Since the purpose of the eddy viscosity is to represent sub-grid processes it is natural to relate the length scale to Δx and the time scale to Δt . Hence the eddy viscosity at scale 4 could be considered in one of the following forms:

$$K_1 \cdot \frac{\Delta x^2}{\Delta t} \quad , \quad K_2 \cdot \Delta x \cdot u \quad , \quad K_3 \cdot \Delta t \cdot u^2$$

In table 2 the 3 different forms of the eddy viscosity for scale 4 have been compared to calibrated results in 5 different situations.

Case	h (m)	u (m/s)	Δx (m)	Δt (s)	$E_{cal.}$ (m^2/s)	K_1	K_2	K_3
A	8	0.7	50	30	1-5	0.06-0.01	0.14-0.03	0.34-0.07
B	20	1.0	500	300	40-50	0.06	0.10	0.17
C	30	0.5	6000	600	≈ 500	0.008	0.17	3.3
D	40	1.0	20	10	1-3	0.075-0.025	0.15-0.05	0.30-0.10
E	1000	0.1	30000	900	≈ 6000	0.006	2.0	667

Table 2 Eddy coefficients of scale 4.

The form $K_2 \cdot \Delta \cdot u$ appears to be promising since K_2 is almost constant in the 5 different cases.

A more advanced approach is the Smagorinski type of eddy viscosity which depends on horizontal gradients of the depth-averaged flow velocity. This approach will be introduced in the following section.

Smagorinski Eddy Viscosity

The Smagorinsky sub-grid model has been widely used and is generally believed to be correct for homogeneous, isotropic turbulence. Various authors have extended this

model to inhomogeneous or anisotropic turbulence, e.g. close to a wall (Schuman, 1975) and to the viscous sub-layer in the boundary layer (Moin and Kim 1982).

The flow equation after filtering out turbulence below the scale Δ , is commonly written

$$\frac{\partial u_i}{\partial t} + \frac{\partial u_i u_j}{\partial x_j} = -\frac{1}{\rho} \frac{\partial P}{\partial x_i} + F_i + \frac{\partial}{\partial x_j} (E \cdot S_{ij}) \quad (1)$$

where $i, j = 1, 2, 3$

u = filtered velocity vector
 P = pressure
 F_i = body forces
 E^i = turbulent eddy viscosity

$$S_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \quad (2)$$

The Smagorinsky sub-grid eddy viscosity takes on the form (cf. Leslie, 1982)

$$E = l^2 (S_{ij} S_{ji})^{\frac{1}{2}} \quad (3)$$

The mixing length l is determined by

$$l = C_s \cdot \Delta x \quad (4)$$

It has been shown by Lilly (1965) and Leonard (1974) that the resultant energy cascade i.e. the dissipation of the large scales is consistent with the Kolmogorov power spectrum and the constant C_s is dependent only on Kolmogorov's universal constant.^s Lilly (1965) used the value $C_s = 0.1825$.

In order to extend the Smagorinsky model to 2-D free surface flow, it is necessary to integrate the flow equations over the vertical.

By analogy to the 3-D form we get,

2-D modelling:

$$\frac{\partial U}{\partial t} - \left[\frac{\partial}{\partial x} (E \cdot \frac{\partial U}{\partial x}) + \frac{1}{2} \frac{\partial}{\partial y} (E (\frac{\partial U}{\partial y} + \frac{\partial V}{\partial x})) \right] \quad (5)$$

where

$$E = l^2 \cdot \left[\left(\frac{\partial U}{\partial x} \right)^2 + \left(\frac{\partial V}{\partial y} \right)^2 + \frac{1}{2} \left(\frac{\partial U}{\partial y} + \frac{\partial V}{\partial x} \right)^2 \right]^{\frac{1}{2}} \quad (6)$$

i.e. the local velocities have simply been replaced by the depth-averaged velocities U and V .

The mixing length is still determined from Eq. (4) but it must be expected that the value of the empirical constant C_s will differ from the values established in 3-D modelling. From the first applications of the model it appears that C_s should be found in the interval 0.4 to 0.8.

Results

Some results from the application of the model to Haraldsund in the Faroe Islands are shown in Figs. 1 and 2. Water depths in the area are up to 60 m while the grid size is only 20 m, so it is certain that bed friction is not the governing factor in the size and intensity of the eddies produced by the model. In such a case, dispersive terms such as those introduced by eddy viscosity should be necessary to produce a realistic flow pattern and have a major effect on the eddies, as is seen in Figs. 1 and 2.

Fig. 1 No eddy viscosity.
Manning Number = 32.

With Zero eddy viscosity a quite unrealistic flow pattern is produced, Fig. 1. In Fig. 2, the results at the same time with $C_s = 0.75$ are much more plausible.

With $C_s = 0.75$, eddy viscosities of 1-2 m^2/s were computed by the Smagorinsky model in regions of maximum velocity gradient, and these are of the correct order of magnitude. Finally, it is reported that the results were very sensitive to the value of C_s . In this and other studies, it seems that $C_s = 0.40$ to 0.80 produces realistic results.

Fig. 2 Smagorinsky eddy, $C_s = 0.75$.
Manning Number = 32.5

CHAPTER 36

PROPAGATION OF WIND WAVES ON TIDES

Hendrik L. Tolman *

abstract

Effects of instationary depths and currents in tides on shelf seas on wind wave propagation are investigated using two numerical models in two academical situations representing shelf sea conditions. It is shown that changes in absolute frequency, which are induced by the instationarity of depth and current, are significant in contrast to what is usually assumed. If these changes are neglected large and unpredictable errors may occur in calculated changes of wavenumber and amplitude.

INTRODUCTION

In the present study the influence of instationary depths and currents on wind generated surface gravity waves, in particular on their propagation, is investigated.

Instationary depths and currents occur when the travel time of waves through some area is of the same order of magnitude as the time scale of the variations in the depth and current field or larger. This is for instance the case for wind waves traveling on tides in shelf seas such as the North Sea. The potential importance of wave-current interactions in such instationary conditions can be illustrated with a measured modulation of significant wave height in the southern North Sea (figure 1), which has the same period as the tide. Since the tidal range is only about 5% of the average depth, current variations (in space and time) rather than depth variations are expected to be responsible for the observed wave height modulations of up to 50 %.

Interactions between waves and currents, in particular the influence of currents on waves, have been studied extensively in the last decades. The importance of these interactions is generally recognized and the subject is treated in many textbooks, e.g. Whitham (1974), Phillips (1977), Mei (1983), review papers, e.g. Peregrine (1976) and

* Delft University of Technology, Department of Civil Engineering,
P.O. box 5048, 2600 GA, Delft, The Netherlands

reports, e.g. Peregrine and Jonsson (1983). However, wave-current interactions are usually considered in small scale (coastal) areas where depths and currents are treated as non-homogeneous and stationary. In such cases the absolute frequency ω of a periodic wave remains constant in space and time. This implies that the number of incoming waves equals the number of outgoing waves (per unit time) for a fixed area. This invariance of absolute frequency is exploited in numerical wave propagation models for stationary depths and currents, e.g. Tayfun et al. (1976) and in calculations of spectral wave transformations due to stationary currents, e.g. Hedges et al. (1985).

In instationary conditions the absolute frequency does not remain constant during propagation as indicated by theory (e.g. Whitham, 1974, his page 383) and observations (Barber, 1949). The governing equations are well known (e.g. Whitham (1974), Mei (1983)). Nevertheless, a constant absolute frequency has been assumed in several models for large scale (and therefore usually instationary) depth and current fields, e.g. Burrows and Hedges (1985), even when it is stated explicitly that depth and current are instationary, e.g. Chen and Wang (1983). Although the subject of instationary wave-current interactions is properly treated in several other publications, e.g. Unna (1941), Barber (1949), Longuet-Higgins and Stewart (1960) and Christoffersen (1982), none of these papers deals explicitly with the influence of the change of absolute frequency on wave-current interactions.

In the present paper the equations for wave propagation on instationary depths and currents and the corresponding changes in wave parameters are summarized. Furthermore interactions are calculated for two academic cases using numerical models. To illustrate the effects of instationarity of depth and current, in particular the change of absolute frequency, calculations are performed for monochromatic waves in a simple one-dimensional geometry. To illustrate such effects in a more realistic situation, calculations are performed for irregular waves in a more complex two-dimensional geometry. For the latter calculations a discrete spectral two-dimensional wave propagation model is used.

H_S (m)

WAVE PROPAGATION ON INSTATIONARY MEDIA

To describe variations in waves due to variations in currents and depths, linear surface gravity waves propagating on a two-dimensional instationary and inhomogeneous depth and current field are considered. Waves are in general characterized with wavenumber (k), absolute frequency (ω), direction (θ) and some amplitude parameter. For monochromatic waves this is the amplitude (a) of the harmonic wave and for short-crested irregular waves this is a two-dimensional spectrum, e.g. the action density spectrum N as a function of ω and θ . If waves on currents are considered, it is convenient to make a distinction between a frame of reference fixed to the bottom, in which the wave frequency is the absolute frequency ω , and a frame of reference moving with the local current velocity \underline{U} , in which the wave frequency is the intrinsic frequency σ . The absolute frequency ω , the intrinsic frequency σ and the wavenumber k are interrelated by the Doppler equation (1) and the dispersion relation (2),

$$\omega = \sigma + \underline{k} \cdot \underline{U} \quad (1)$$

$$\sigma = \{ gk \tanh(kd) \}^{\frac{1}{2}} \quad (2)$$

where \underline{k} is the wavenumber vector, defined by k and θ , g is the acceleration of gravity and d is the water depth.

In the following a Lagrangian viewpoint is taken in which wave energy is followed during propagation. In a frame of reference moving with the local current velocity \underline{U} the propagation velocity of wave energy c_g (direction θ) is given by the linear theory as :

$$c_g = \frac{\partial \sigma}{\partial k} = \frac{\sigma}{k} n \quad (3)$$

in which

$$n = \frac{1}{2} + \frac{kd}{\sinh 2kd} \quad (4)$$

In the fixed frame the propagation velocity of the energy (\underline{c}_w) is (e.g. Phillips, 1977) :

$$\underline{c}_w = \underline{c}_g + \underline{U} \quad (5)$$

The corresponding rates of change in absolute frequency ω , intrinsic frequency σ , wavenumber k and direction θ (denoted as $d\omega/dt$, $d\sigma/dt$, dk/dt and $d\theta/dt$ respectively) can be determined using equations (1), (2) and the conservation of waves $\partial k/\partial t + \partial \omega/\partial x = 0$ (e.g. Whitham (1974), his page 11). These rates of change are (e.g. Christoffersen (1982), Mei (1983), his page 96) :

$$\frac{d\omega}{dt} = \frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial t} + \underline{k} \cdot \frac{\partial \underline{U}}{\partial t} \quad (6)$$

$$\frac{dk}{dt} = - \frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial s} - \underline{k} \cdot \frac{\partial \underline{U}}{\partial s} \quad (7)$$

$$\frac{d\sigma}{dt} = \frac{\partial \sigma}{\partial d} \left(\frac{\partial d}{\partial t} + \underline{U} \cdot \nabla d \right) - c_g \underline{k} \cdot \frac{\partial \underline{U}}{\partial s} \quad (8)$$

$$\frac{d\theta}{dt} = - \frac{1}{k} \frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial m} - \frac{\underline{k}}{k} \cdot \frac{\partial \underline{U}}{\partial m} \quad (9)$$

in which s is a coordinate in the direction θ , m a coordinate perpendicular to s and ∇ the differential operator in space. The operator d/dt is defined as :

$$\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \underline{c}_w \cdot \nabla \quad (10)$$

The calculation of wave amplitudes for propagation over currents in absence of energy sources and sinks (wave generation and dissipation e.g. by wind) is based on the conservation of action (e.g. Whitham 1974, Phillips, 1977). The formulation of the action conservation for monochromatic waves differs from that for irregular waves. For monochromatic waves the (Eulerian) action conservation equation is written as :

$$\frac{\partial A}{\partial t} + \nabla \cdot (\underline{c}_w A) = 0 \quad (11)$$

where wave action density A is related to energy density E and amplitude a :

$$A = E/\sigma \quad (12)$$

$$E = \frac{1}{2} \rho g a^2 \quad (13)$$

For short-crested irregular waves the action conservation equation is written as :

$$\frac{\partial N}{\partial t} + \nabla \cdot (\underline{c}_w N) + \frac{\partial}{\partial \theta} (c_\theta N) + \frac{\partial}{\partial \omega} (c_\omega N) = 0 \quad (14)$$

where the action density spectrum $N(\omega, \theta)$ (action per unit surface, frequency and direction) is related to the energy density spectrum $F(\omega, \theta)$:

$$N(\omega, \theta) = F(\omega, \theta) / \sigma \quad (15)$$

As amplitude parameter of the irregular waves the significant wave height H_S is used, which is calculated from the energy density spectrum as

$$H_S = 4.0 \left(\iint F(\omega, \theta) d\omega d\theta \right)^{\frac{1}{2}} / \rho g \quad (16)$$

The first term in equation (14) represents the local variation in time, which is balanced by the other terms which represent different forms of convection. The first of these represents convection in space (including shoaling), where c_w is given as in equation (5). It corresponds to the second term in equation (11) for monochromatic waves. The third term in equation (14) represents refraction where c_θ equals $d\theta/dt$ as given in equation (9). These first three terms are quite common for models which consider only stationary propagation conditions. The fourth term is unique for instationary depths and currents. It represents transport of action over the spectral frequencies, which corresponds to the change of absolute frequency in a monochromatic case. Its formulation is analogous to the above spectral representation of refraction, where the change of wave direction is represented by transport of action over the spectral directions. The propagation velocity c_w equals $d\omega/dt$ as given in equation (6).

Based on equation (6), which is formulated in terms of time derivatives, the importance of the instationarity can be expressed in terms of the (relative) change of absolute frequency $\Delta\omega/\omega$. Likewise, the importance of the inhomogeneity can be expressed in the (relative) change of wavenumber $\Delta k/k$, based on equation (7). The ratio between the relative change in absolute frequency $\Delta\omega/\omega$ and the relative change in wavenumber $\Delta k/k$ can therefore be used to assess the importance of the instationarity compared to the importance of the inhomogeneity.

MONOCHROMATIC ONE-DIMENSIONAL SITUATION

To illustrate the influence of instationary depth and current variations on waves, consider monochromatic waves in a one-dimensional geometry. The current field (representing a tide) consists of a one-dimensional long wave over a constant bottom level. The tide propagates in the positive x-direction and its characteristics are described as :

$$d(x,t) = d_0 + A_d \sin \chi(x,t) \quad (17)$$

$$U(x,t) = A_U \sin \chi(x,t) \quad (18)$$

$$\chi(x,t) = Kx - \Omega t \quad (19)$$

$$c_t = \Omega/K = (gd_0)^{\frac{1}{2}} \quad (20)$$

$$A_U/A_d = (g/d_0)^{\frac{1}{2}} \quad (21)$$

In these equations χ is the tidal phase, c_t is the propagation velocity of the tide, K and Ω are the wavenumber and frequency of tide and A_U and A_d are the current and depth amplitude respectively (current velocity constant over depth).

The calculations for the above situation are carried out as follows. Absolute frequency ω as a function of x and t is calculated by simultaneous integration of $dx/dt = c_w$ and $d\omega/dt$ as given by (6), starting at a situation with $\chi = 0$ (no current, suffix o). Using ω , d and U the parameters needed for this integration (k and c_g) can be calculated using equations (1) through (4). As it can be shown that for the considered situation ω , k , A etc. vary with x and t through χ only, action density A is stationary in a frame of reference which moves with the propagation velocity of the tide c_t . Using this property, the action conservation equation (11) can be rewritten as :

$$\frac{\partial}{\partial x} ((c_w - c_t) A) = 0 \quad (22)$$

so that the relative action density A/A_0 can be calculated as :

$$\frac{A}{A_0} = \frac{c_{w,o} - c_t}{c_w - c_t} \quad (23)$$

The wave energy and amplitude are subsequently calculated from the relative action density using equations (23), (12) and (13).

Figure 2 (solid lines) shows the results of calculations for conditions roughly representing the M_2 tide in the southern North Sea ($\omega_0 = 2\pi/10$ rad/s, period of the tide = 12 h, $d_0 = 25$ m, $A_d = 1$ m resulting in $AJ = 0.63$ m/s). Calculated values of wave parameters are basically a function of the phase χ of the tide, but they are presented in figure 2 as they appear at a fixed location as a function of time. This transformation from phase χ to time t is easily performed using equations (19) and (20). This figure shows variations in the normalized absolute frequency (ω/ω_0) which cannot be neglected compared to variations in the normalized wavenumber (k/k_0). Consequently both in stationarity and inhomogeneity are important for the situation considered. Similar results were obtained for tide and waves traveling in opposite directions and for other depths, wave frequencies and depth and current oscillation amplitudes.

If the change in absolute frequency is neglected ($d\omega/dt = 0$, dashed lines in figure 2), large errors in calculated wavenumbers and amplitudes occur. If tide and waves travel in opposite directions (c_t and c_w with opposite signs, not shown here), such an approach overestimates the change of wavenumber by a factor of 2 or more. For tide and waves traveling in the same direction (figure 2) the situation is even worse as the predicted sign of the variation of the wavenumber is always wrong; the thus predicted variation of the amplitude also shows large errors which can include wrong signs.

Fig. 2 Results of calculations with simple one-dimensional model for monochromatic waves, tidal period 12 h, $\omega_0 = 2\pi/10$ rad/s, $d_0 = 25$ m, $A_d = 1$ m and $AJ = 0.63$ m/s. — $d\omega/dt$ given by equation 6, - - - $d\omega/dt = 0$ a) normalized absolute frequency ω/ω_0 b) normalized wavenumber k/k_0 c) normalized amplitude a/a_0 .

SPECTRAL TWO-DIMENSIONAL SITUATION

Wave-current interactions in more realistic situations should be determined using a spectral approach based on equation (14). In the following the spectral development of a wave field is calculated using a numerical model in which equation (14) is approximated using a finite difference approach. The model will be described elsewhere. It suffices to say that it is approximately second order accurate in all five dimensions (\underline{x} , ω , θ , t).

Again a situation is considered which roughly represents the M_2 tide in the North Sea (figure 3). The area ($500 \times 750 \text{ km}^2$) is discretized using a square grid with spatial increments of 25 km. The action density spectrum is discretized with 24 directions (directional increment 15°) and 18 frequencies ranging from 0.05 Hz to 0.30 Hz (exponential distribution). The time step in the integration is 15 min. Current and depth fields are calculated using a two-dimensional depth integrated current model, which includes Coriolis forces (Coriolis parameter constant as for 53° N) and bottom friction (Chezy coefficient $C = 18 \log(-120 d_0)$). A periodic surface elevation with amplitude of 0.25 m and a period of 12 h was applied to the open boundary to

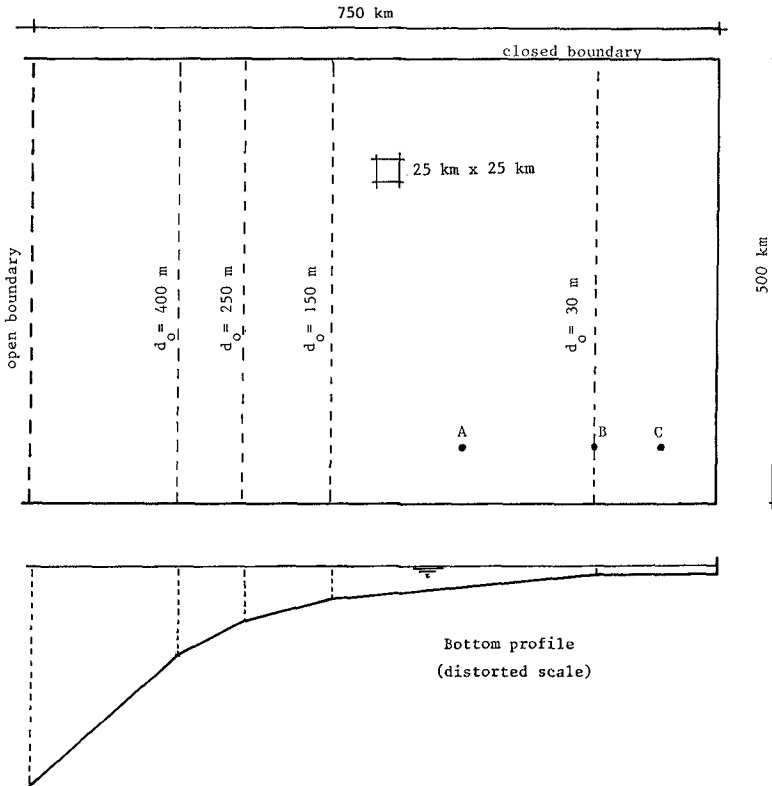

Fig. 3 Layout of academical shelf sea as used in the spectral two-dimensional calculations

simulate the M_2 tide. The resulting tide travels counterclockwise through the area considered with resulting maximum current velocities as shown in figure 4. A stationary energy density spectrum was imposed at the open boundary. The mean wave direction is perpendicular to the boundary. The spectral shape is that of a Gaussian distribution over the frequencies and $\cos^2(\theta)$ over the directions (average frequency 0.1 Hz, frequency spread 0.015 Hz). After a few days of simulation depth, current and wave spectra are periodic with an oscillation period of 12 hours. All results presented next refer to the periodic solution.

Figure 5 shows the spatial distribution of the range of local variation in time of some spectral parameters (e.g. $H_{S,max} - H_{S,min}$). These parameter values are normalized with their local value averaged over the tidal period (suffix a, e.g. $H_{S,a}$). Presented are : a) mean absolute frequency defined as

$$\bar{\omega} = \frac{\iint \omega F(\omega, \theta) d\omega d\theta}{\iint F(\omega, \theta) d\omega d\theta} \quad (24)$$

b) mean wavenumber, defined as

$$\bar{k} = \frac{\iint k F(\omega, \theta) d\omega d\theta}{\iint F(\omega, \theta) d\omega d\theta} \quad (25)$$

and c) significant wave height, see equation (16).

To illustrate the behaviour in time of several wave parameters and the nature of the errors which are made if the change in absolute frequency is neglected, results are given in figure 6 for three locations in the area with large variations in wave parameters (figures 3 and 5). They have been selected to illustrate the phase lags between the local current velocity and e.g. the variation of wavenumber. These lags vary with location, which indicates that it is a cumulative effect, not a local one.

Essentially the above calculations with the two-dimensional model have to be repeated with $d\omega/dt = 0$ to determine the errors then made.

Fig. 4 Maximum current velocities of M_2 tide in shelf sea of fig. 3.

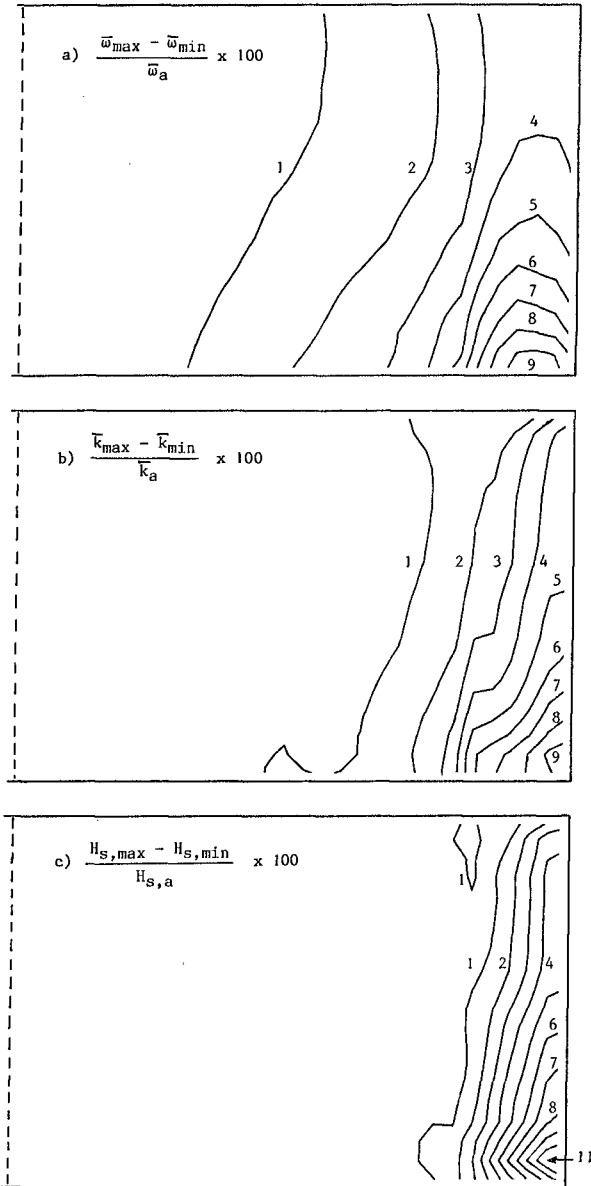

Fig. 5 Normalized ranges of variation of a) absolute frequency $\bar{\omega}/\bar{\omega}_a$ b) wavenumber \bar{k}/\bar{k}_a and c) significant wave height $H_s/H_{s,a}$ for spectral two-dimensional calculations (distribution over area of figure 3).

As these calculations are quite expensive (approximately 1.5 hours CPU time on an IBM 3083-JX1) they have not been performed. However, the mean absolute frequency now (approximately) equals the stationary mean absolute frequency at the input boundary $\bar{\omega}_b$. Furthermore the (input) spectrum is extremely narrow banded and can therefore be described with a single wavenumber \bar{k} and frequency $\bar{\omega}$ which approximately satisfy equations (1) and (2). Thus the wavenumber as obtained when the absolute frequency is assumed to be constant can be estimated using equations (1) and (2) with $\bar{\omega} = \bar{\omega}_b$, $k = \bar{k}$ and $\underline{k} \cdot \underline{U} = \bar{k}U'$ where U' is the current velocity in the mean propagation direction of the waves. For the calculation of action density and significant waveheight, which includes integrating equation (14), no simple approximation is available. The solid lines in figure 6 represent results of the two-dimensional calculations (including frequency shifts) and the dashed lines represent the approximate solutions as obtained when the change in absolute frequency is neglected.

Fig. 6 Parameter values for points A, B, and C of figure 3 as a function of time, — $d\omega/dt$ according to equation 6 (in-stationary), - - - $d\omega/dt = 0$ (quasi-stationary) : a) Current velocity in propagation direction of waves U' , b) normalized absolute frequency $\bar{\omega}/\bar{\omega}_a$ and c) normalized wavenumber \bar{k}/\bar{k}_a .

DISCUSSION

The results of calculations for monochromatic waves in the one-dimensional case (figure 2) clearly show the influence of instationarity of depth and current on changes in absolute frequency, wavenumber and wave amplitude. In particular the change in absolute frequency is significant. Its normalized change is of the same order of magnitude as the normalized change in wavenumber or larger. This indicates that in this case instationarity is at least as important as inhomogeneity.

The results of calculations with the spectral two-dimensional wave propagation model for the academical shelf sea of figure 3 confirm these findings. Figure 5 a) shows that variations in absolute frequency are not negligible, specially in shallow water areas with relatively strong currents (see figure 4). Again normalized changes of absolute frequency (figure 5a) are of the same order of magnitude as normalized changes of wavenumber (figure 5b), indicating the importance of instationarity. Finally variations in significant wave height (figure 5c) are significant.

If the absolute frequency is assumed to be constant ($d\omega/dt = 0$), large errors occur in the predicted change of wavenumber, both in the one- and two-dimensional situations considered. Similar errors are expected to occur for the significant waveheight in the two-dimensional situation. They do occur for the change of amplitude in the one-dimensional situation. Unfortunately such errors cannot be estimated from calculations based on the assumption of constant absolute frequency, as will be shown next. In instationary conditions the change of wave parameters depends on the (local) change of absolute frequency. This change in turn depends on depth and current conditions along the propagation path of the wave energy. Due to these accumulated effects the local current is not correlated with the local wave parameters such as the wavenumber (see solid lines of figure 6 a and c). If the shift in absolute frequency is neglected, the cumulative effects disappear and the local current and variations in e.g. wavenumber depend on local parameters only (see dashed lines in figure 6c). As the cumulative effects can usually not be estimated from local parameters only, errors thus made cannot be estimated.

Wave-current interactions not only affect propagation but also generation and dissipation. Therefore work is in progress to add these interactions to the above two-dimensional model. This model will be used to determine the influence of tide and storm surge induced wave-current interactions in the North sea. A description of this model and results of this continued effort will be published elsewhere.

CONCLUSIONS

In this study it is shown that instationary depth and current fields such as tides in shelf seas induce significant variations of the absolute frequency of (wind) waves. These variations are not only induced by local depth and current variations but also by the structure of the depth and current field in space and time. The commonly used quasi-stationary approach, in which the absolute frequency is assumed to remain constant during propagation, can lead to significant errors in the calculated variations in wavenumber and amplitude at least for the fairly typical shelf sea conditions considered in this study.

CHAPTER 37

ON JOINT DISTRIBUTION OF WAVE HEIGHTS AND DIRECTIONS

Masahiko Isebe*; M. JSCE, M. ASCE

In the individual wave analysis of short-crested irregular waves, the wave direction of an individual wave is an important quantity as well as the wave height and period. In this paper, the joint probability density of the wave height and direction is derived theoretically on the assumption of a narrow-banded frequency spectrum. A field experiment was carried out to examine the validity of the theory. The measured joint distribution agreed well with that predicted by the theory.

1. INTRODUCTION

It is of great importance to describe random sea states with sufficient accuracy. Two major methodologies in the analysis of irregular waves are the spectral analysis and individual wave analysis.

In the spectral analysis, irregular waves are regarded as a superposition of component regular waves with various frequencies and directions. From the expected values of the component wave energies, an energy spectrum is defined. Based on the concept of superposition, this analysis method is especially valid as applied to linear phenomena.

On the other hand, in the individual wave analysis, an irregular wave train is decomposed into successive individual waves defined by a zero-crossing method or others. An individual wave is usually regarded as a part of a regular wave train with the same height, period and direction. Hence, various properties of the individual wave such as the surface profile, water particle velocity and pressure can be calculated by applying a nonlinear regular wave theory. This method may not be appropriate in deep water because waves are dispersive and hence an individual wave cannot be independent of the adjoining individual waves. However, in shallow water where wave dispersion is not so rapid, we can even make a nonlinear analysis

* Associate Professor, Department of Civil Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan

employing this analysis procedure.

Irregular waves are either uni-directional or multi-directional, in other terms, long-crested or short-crested. In the spectral analysis of long-crested irregular waves, the frequency spectrum is defined as the energy density with respect to frequency, and used to describe the characteristics of the wave field. On the other hand, in the individual wave analysis of long-crested irregular waves, the distribution of wave heights or the joint distribution of wave heights and periods is used. For short-crested irregular waves, the spectral analysis is made by introducing the directional spectrum which represents the energy density with respect to frequency and direction. Much effort has been devoted through theoretical and experimental works to extend basic and practical knowledge in these categories. However, the individual wave analysis of short-crested irregular waves, in which the distribution of directions should also be discussed, remains to be developed. If a theory is established in this category, it will be of practical use because it will allow to evaluate the nonlinear actions of short-crested irregular waves such as wave forces and sediment transport.

The main purpose of this study is to derive a joint probability density of wave height and direction. The envelope functions of the water surface elevation and the two components of horizontal water particle velocity are introduced to define the wave height and direction, on the assumption that the frequency spectrum is narrow-banded. Among possible definitions of wave direction of an individual wave, a definition similar to the mean direction is employed. Examples of the joint density are depicted. The present theory is examined through comparison with the result of a field experiment.

2. THEORY

2.1 Envelope Functions

Wave direction may be defined in many ways. Among them, the propagation direction of the wave crest, the direction of the surface slope, and the direction of the water particle velocity are promising candidates from a practical point of view. In the present study, the two components of horizontal water particle velocity as well as the water surface fluctuation are used for the definition. This will make it more easy to apply the result to the evaluation of wave force, sediment transport, breaking criterion, and others. In addition, the theory can easily be examined by field experiments.

Short-crested irregular waves consist of an infinite number of component waves with various periods and directions. Let the i 'th component of frequency be f_i and the j 'th component of direction θ_j , then the time series of the water surface elevation, η , at the location, (x, y) , and the two components, u and v , of horizontal water particle velocity in the x - and y - direction can be expressed as

$$\left. \begin{aligned} \eta(t) &= \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} c_{ij} \cos \phi_{ij} \\ u(t) &= \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} \hat{H}_i \cos \theta_j \cdot c_{ij} \cos \phi_{ij} \\ v(t) &= \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} \hat{H}_i \sin \theta_j \cdot c_{ij} \cos \phi_{ij} \end{aligned} \right\} \quad (1)$$

$$\phi_{ij} = k_i(x \cos \theta_j + y \sin \theta_j) - 2\pi f_i t - \varepsilon_{ij} \quad (2)$$

$$\hat{H}_i = 2\pi f_i \frac{\cosh k_i z}{\sinh k_i h} \quad (3)$$

where c_{ij} and ε_{ij} , respectively, denote the amplitude and phase angle of component waves which represent the frequency range Δf_i and direction range $\Delta \theta_j$. The quantity h is the water depth, z the elevation from the bottom, k_i the wave number determined from f_i by the dispersion relation, and t the time. From the definition, the amplitude is related to the directional spectrum, $S(f, \theta)$, as

$$\langle c_{ij}^2 \rangle / 2 = S(f_i, \theta_j) \Delta f_i \Delta \theta_j \quad (4)$$

where $\langle \rangle$ denotes the expected value. The phase angle, ε_{ij} , has a uniform distribution between 0 to 2π .

Here, we assume that the frequency spectrum is narrow-banded. Then f_i can be expressed as the sum of the mean frequency, \bar{f} , and a small deviation, f'_i :

$$f_i = \bar{f} + f'_i \quad (5)$$

On substituting Eqs. (2) and (5) into Eq. (1) and with use of the additional formulas of the trigonometric functions, the following expressions can be obtained:

$$\left. \begin{aligned} \eta(t) &= \eta_0 \cos 2\pi \bar{f} t + \eta_s \sin 2\pi \bar{f} t \\ u(t) &= u_c \cos 2\pi \bar{f} t + u_s \sin 2\pi \bar{f} t \\ v(t) &= v_c \cos 2\pi \bar{f} t + v_s \sin 2\pi \bar{f} t \end{aligned} \right\} \quad (6)$$

where η_0 , u_c , v_c , etc. are slowly-varying envelope functions defined by

$$\left. \begin{aligned} \eta_0 &= \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} c_{ij} \cos \phi'_{ij} \\ u_c &= \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} \hat{H}_i \cos \theta_j \cdot c_{ij} \cos \phi'_{ij} \\ v_c &= \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} \hat{H}_i \sin \theta_j \cdot c_{ij} \cos \phi'_{ij} \end{aligned} \right\} \quad (7)$$

$$\phi'_{ij} = k_i(x \cos \theta_j + y \sin \theta_j) - 2\pi f'_i t - \varepsilon_{ij} \quad (8)$$

The envelope functions, η_s , u_s and v_s , are defined by substituting $\cos \phi'_{ij}$ by $\sin \phi'_{ij}$ on the right hand side of Eq. (7).

In Longuet-Higgins (1952), the probability density of wave height was determined from the envelope function of the water surface elevation. In the present study, the six envelope functions, η_c , η_s , u_c , u_s , v_c and v_s , determine the wave height and phase lags among the water surface fluctuation and the two components of horizontal water particle velocity of an individual wave. Hence, the joint density of these quantities determines the joint density of the wave height and direction of an individual wave.

The quantity, ϵ_{ij} , and hence ϕ'_{ij} are uniformly distributed random quantities. By applying the central limit theorem to Eq. (7) and the corresponding equations for η_s , u_s and v_s , all the six quantities are found to have normal distributions. Therefore, the joint density can be determined from the moments up to the second order. The moments of the first order, which are the mean values, vanish from the definition. The moments of the second order, which are variances and covariances, are expressed from Eqs. (1) and (7) as follows:

$$\left. \begin{aligned} \langle \eta_c^2 \rangle &= \langle \eta_s^2 \rangle = \langle \eta^2 \rangle \equiv m_{00}, & \langle \eta_c u_c \rangle &= \langle \eta_s u_s \rangle = \langle \eta u \rangle \equiv m_{10} \\ \langle u_c^2 \rangle &= \langle u_s^2 \rangle = \langle u^2 \rangle \equiv m_{20}, & \langle \eta_c v_c \rangle &= \langle \eta_s v_s \rangle = \langle \eta v \rangle \equiv m_{01} \\ \langle v_c^2 \rangle &= \langle v_s^2 \rangle = \langle v^2 \rangle \equiv m_{02}, & \langle u_c v_c \rangle &= \langle u_s v_s \rangle = \langle uv \rangle \equiv m_{11} \end{aligned} \right\} \quad (9)$$

The covariances for the combination of the subscripts, c and s , such as $\langle \eta_c \eta_s \rangle$ vanish, which means they are independent of each other. With a definition, $(\eta_c, u_c, v_c, \eta_s, u_s, v_s) = (\xi_1, \xi_2, \xi_3, \xi_4, \xi_5, \xi_6)$, the covariance matrix, M , is summarized as

$$M = [\langle \xi_i \xi_j \rangle] = \begin{bmatrix} M_3 & 0 \\ 0 & M_3 \end{bmatrix} \quad (10)$$

$$M_3 = \begin{bmatrix} m_{00} & m_{10} & m_{01} \\ m_{10} & m_{20} & m_{11} \\ m_{01} & m_{11} & m_{02} \end{bmatrix} \quad (11)$$

In general, the multi-dimensional normal distribution is written as

$$p(\xi_1, \xi_2, \dots, \xi_n) = \frac{1}{(2\pi)^{n/2} \sqrt{|M|}} \exp \left[-\frac{1}{2} \left(\sum_{i=1}^n \sum_{j=1}^n \xi_i M_{ij}^{-1} \xi_j \right) \right] \quad (12)$$

(Rice, 1944). From Eqs. (10) and (11)

$$|M| = (m_{00} m_{20} m_{02} A)^2 \quad (13)$$

$$M^{-1} = \frac{1}{A} \begin{bmatrix} M'_3 & 0 \\ 0 & M'_3 \end{bmatrix} \quad (14)$$

$$M'_3 = \begin{bmatrix} \frac{1-r_{11}^2}{m_{00}} & -\frac{r_{10}-r_{01}r_{11}}{\sqrt{m_{00}m_{20}}} & -\frac{r_{01}-r_{10}r_{11}}{\sqrt{m_{00}m_{02}}} \\ -\frac{r_{10}-r_{01}r_{11}}{\sqrt{m_{00}m_{20}}} & \frac{1-r_{01}^2}{m_{20}} & -\frac{r_{11}-r_{10}r_{01}}{\sqrt{m_{20}m_{02}}} \\ -\frac{r_{01}-r_{10}r_{11}}{\sqrt{m_{00}m_{02}}} & -\frac{r_{11}-r_{10}r_{01}}{\sqrt{m_{20}m_{02}}} & \frac{1-r_{10}^2}{m_{02}} \end{bmatrix} \quad (15)$$

where

$$A = 1 + 2r_{10}r_{01}r_{11} - r_{10}^2 - r_{01}^2 - r_{11}^2 \quad (16)$$

$$r_{10} = m_{10}/\sqrt{m_{00}m_{20}} \quad (17)$$

$$r_{01} = m_{01}/\sqrt{m_{00}m_{02}} \quad (18)$$

$$r_{11} = m_{11}/\sqrt{m_{20}m_{02}} \quad (19)$$

and hence Eq. (12) becomes

$$\begin{aligned} & p(\eta_c, u_c, v_c, \eta_s, u_s, v_s) \\ &= \frac{1}{(2\pi)^3 m_{00} m_{20} m_{02} A} \\ & \times \exp \left[-\frac{1}{2A} \left\{ (1-r_{11}^2) \frac{\eta_c^2 + \eta_s^2}{m_{00}} + (1-r_{01}^2) \frac{u_c^2 + u_s^2}{m_{20}} \right. \right. \\ & \quad + (1-r_{10}^2) \frac{v_c^2 + v_s^2}{m_{02}} - 2(r_{10}-r_{01}r_{11}) \frac{\eta_c u_c + \eta_s u_s}{\sqrt{m_{00}m_{20}}} \\ & \quad \left. \left. - 2(r_{01}-r_{10}r_{11}) \frac{\eta_c v_c + \eta_s v_s}{\sqrt{m_{00}m_{02}}} - 2(r_{11}-r_{10}r_{01}) \frac{u_c v_c + u_s v_s}{\sqrt{m_{20}m_{02}}} \right\} \right] \quad (20) \end{aligned}$$

Here, we take the x -axis in the principal wave direction. Then $m_{11}=0$, and hence $r_{11}=0$. Furthermore, non-dimensional variables are introduced by

$$\begin{aligned} N_c &= \eta_c/\sqrt{m_{00}}, & U_c &= u_c/\sqrt{m_{20}}, & V_c &= v_c/\sqrt{m_{02}} \\ N_s &= \eta_s/\sqrt{m_{00}}, & U_s &= u_s/\sqrt{m_{20}}, & V_s &= v_s/\sqrt{m_{02}} \end{aligned} \quad (21)$$

Since

$$\begin{aligned} & d\eta_c du_c dv_c d\eta_s du_s dv_s \\ &= m_{00} m_{20} m_{02} dN_c dU_c dV_c dN_s dU_s dV_s \end{aligned} \quad (22)$$

Eq. (20) becomes

$$\begin{aligned} & p(N_c, U_c, V_c, N_s, U_s, V_s) \\ &= \frac{1}{(2\pi)^3 A} \exp \left[-\frac{1}{2A} \left\{ N_c^2 + N_s^2 + (1-r_{01}^2)(U_c^2 + U_s^2) + (1-r_{10}^2)(V_c^2 + V_s^2) \right. \right. \\ & \quad \left. \left. - 2r_{10}(N_c U_c + N_s U_s) - 2r_{01}(N_c V_c + N_s V_s) + 2r_{10}r_{01}(U_c V_c + U_s V_s) \right\} \right] \quad (23) \end{aligned}$$

where from Eq. (16) with $r_{11}=0$

$$A = 1 - r_{i0}^2 - r_{o1}^2 \tag{24}$$

2.2 Change of Reference Phase

From the cos and sin components of the envelope functions, the amplitudes and phase angles of the water surface fluctuation and particle velocity of an individual wave can be determined. To take the phase angle, δ , of the water surface elevation as a reference phase, we shift the phases of the three wave properties by δ :

$$\begin{aligned} N_o &= N_p \cos \delta, & U_c &= U_p \cos \delta - U_q \sin \delta, & V_c &= V_p \cos \delta - V_q \sin \delta \\ N_s &= N_p \sin \delta, & U_s &= U_p \sin \delta + U_q \cos \delta, & V_s &= V_p \sin \delta + V_q \cos \delta \end{aligned} \tag{25}$$

where the subscript, p , denotes the component which is in phase with the water surface fluctuation, and the subscript, q , the component which is 90° out of the phase. The above transformation of variables implies

$$dN_o dU_c dV_c dN_s dU_s dV_s = N_p dN_p d\delta dU_p dU_q dV_p dV_q \tag{26}$$

Hence, Eq. (23) is transformed as

$$\begin{aligned} & p(N_p, \delta, U_p, U_q, V_p, V_q) \\ &= \frac{N_p}{(2\pi)^3 A} \exp \left[-\frac{1}{2A} \{ N_p^2 + (1 - r_{o1}^2)(U_p^2 + U_q^2) + (1 - r_{i0}^2)(V_p^2 + V_q^2) \right. \\ & \quad \left. - 2r_{i0}N_pU_p - 2r_{o1}N_pV_p + 2r_{i0}r_{o1}(U_pV_p + U_qV_q) \} \right] \end{aligned} \tag{27}$$

Since the right hand side of the above equation is independent of δ , $p(N_p, U_p, U_q, V_p, V_q)$ can be obtained by simply multiplying it by 2π .

Fig. 1 The path lines of the water surface elevation and the vector of the horizontal water particle velocity.

Figure 1 depicts the physical meaning of the above parameters. The parameters are shown in dimensional form as η_p , u_p , u_q , v_p and v_q . In general, the water surface elevation oscillates sinusoidally and the velocity vector, (u, v) , moves along an ellipse. The principal axis of the ellipse represents the velocity vector at the time of its maximum magnitude. Its direction does not necessarily coincide with the direction of the water particle velocity at the time of the maximum water surface elevation. The former one corresponds to the principal wave direction since it is the direction of the principal axis. The latter one corresponds to the mean wave direction since it is defined from the ratio of the two components of water particle velocity which are in phase with the water surface fluctuation. These two directions are candidates of the definition of the individual wave direction. The appropriate definition depends on the problem in which the distribution is used. In this study, the definition similar to the mean direction is employed for the sake of simplicity.

Since the wave direction is independent of U_q and V_q in this definition, Eq. (27) is integrated with respect to U_q and V_q to yield

$$p(N_p, U_p, V_p) = \frac{N_p}{2\pi\sqrt{A}} \exp \left[-\frac{1}{2A} \{N_p^2 + (1-r_{01}^2)U_p^2 + (1-r_{10}^2)V_p^2 - 2r_{10}N_pU_p - 2r_{01}N_pV_p + 2r_{10}r_{01}U_pV_p\} \right] \quad (28)$$

2.3 Joint Density of Wave Height and Direction

Since the wave direction is defined by $\alpha = \tan^{-1}(v_p/u_p)$ in the present study, (U_p, V_p) are transformed to the polar coordinates, (W, α) :

$$U_p = W \cos \alpha, \quad V_p = (W/\gamma) \sin \alpha \quad (29)$$

where γ is the correction factor which compensates the distortion resulted through the non-dimensionalization. This is expressed from Eq. (21) by

$$\gamma = \sqrt{m_{02}/m_{20}} \quad (30)$$

Thus γ is found to be the long-crestedness parameter. From Eq. (29)

$$dU_p dV_p = (W/\gamma) dW d\alpha \quad (31)$$

Hence, Eq. (28) becomes

$$\begin{aligned}
 p(N_p, W, \alpha) &= \frac{N_p W}{2\pi\sqrt{D}\gamma} \exp \left[-\frac{1}{2D} \left\{ N_p^2 + (1-r_{01}^2)W^2 \cos^2 \alpha + (1-r_{10}^2)W^2 \frac{\sin^2 \alpha}{\gamma^2} \right. \right. \\
 &\quad \left. \left. - 2r_{10}N_p W \cos \alpha - 2r_{01}N_p W \frac{\sin \alpha}{\gamma} + 2r_{10}r_{01}W^2 \cos \alpha \frac{\sin \alpha}{\gamma} \right\} \right] \quad (32)
 \end{aligned}$$

Since N_p and α are the non-dimensional amplitude (half wave height) and direction of an individual wave, the joint probability density of wave height and direction can be obtained by integrating the above equation from 0 to ∞ with respect to W . This can be done by using the following relationship:

$$\begin{aligned}
 &\int_0^\infty W \exp \left[-\frac{1}{2D} (aW^2 - 2bN_p W) \right] dW \\
 &= \frac{D}{a} + \frac{\sqrt{D} b N_p}{a^{3/2}} \exp \left[\frac{1}{2D} \frac{b^2 N_p^2}{a} \right] \sqrt{\frac{\pi}{2}} \left(1 + \operatorname{erf} \left(\frac{b N_p}{\sqrt{D a}} \right) \right) \quad (33)
 \end{aligned}$$

where erf denotes the error function defined by

$$\operatorname{erf}(\zeta) = \sqrt{\frac{2}{\pi}} \int_0^\zeta \exp \left(-\frac{\zeta'^2}{2} \right) d\zeta' \quad (34)$$

The result of the integration is as follows:

$$\begin{aligned}
 p(N_p, \alpha) &= \frac{1}{2\pi\gamma} \left\{ \frac{\sqrt{D}}{a} N_p \exp \left[-\frac{N_p^2}{2D} \right] \right. \\
 &\quad \left. + \frac{b}{a^{3/2}} N_p^2 \exp \left[-\frac{1}{2} \frac{c}{a} N_p^2 \right] \sqrt{\frac{\pi}{2}} \left(1 + \operatorname{erf} \left(\frac{b N_p}{\sqrt{D a}} \right) \right) \right\} \quad (35)
 \end{aligned}$$

where

$$\left. \begin{aligned}
 a &= (1-r_{01}^2) \cos^2 \alpha + 2r_{10}r_{01} \cos \alpha \frac{\sin \alpha}{\gamma} + (1-r_{10}^2) \frac{\sin^2 \alpha}{\gamma^2} \\
 b &= r_{10} \cos \alpha + r_{01} \frac{\sin \alpha}{\gamma} \\
 c &= \cos^2 \alpha + \frac{\sin^2 \alpha}{\gamma^2}
 \end{aligned} \right\} \quad (36)$$

We see from the above result that the joint probability density, $p(N_p, \alpha)$, of wave amplitude and direction can completely be determined from r_{10} , r_{01} and γ . Figure 2 shows some examples of the joint density.

When the directional distribution is narrow and symmetrical, $r_{10} \rightarrow 1$ and $r_{01} = 0$. Then Eq. (35) is simplified as

$$p(N_p, \alpha) = \frac{1}{\sqrt{2\pi}\gamma} \frac{N_p^2}{\cos^2 \alpha} \exp \left[-\frac{1}{2} \left(1 + \frac{\tan^2 \alpha}{\gamma^2} \right) N_p^2 \right] \quad (\cos \alpha > 0) \quad (37)$$

Fig. 2 Examples of the joint probability density of wave height and direction.

In this case, the mean wave height, $2\bar{N}_p(\alpha)$, for a fixed wave direction defined by

$$2\bar{N}_p(\alpha) = 2 \int_0^\infty N_p p(N_p, \alpha) dN_p / \int_0^\infty p(N_p, \alpha) dN_p \tag{38}$$

can be obtained analytically as

$$2\bar{N}_p(\alpha) = 8 / \sqrt{2\pi \left(1 + \frac{\tan^2 \alpha}{\gamma^2}\right)} \tag{39}$$

This shows that the mean wave height decreases as the direction shifts away from the principal direction.

2.4 Joint Density of Two Components of Water Particle Velocity

In this section, we derive the joint probability density, $p(U_p, V_p)$, of the two components of water particle velocity at the time of maximum water surface elevation. For this purpose, we have only to integrate Eq. (28) from 0 to ∞ with respect to N_p . By using Eq. (33) in the derivation, the following result can be obtained:

$$p(U_p, V_p) = \frac{1}{2\pi} \left[\sqrt{A} \exp \left[-\frac{1}{2A} \{ (1-r_{01}^2)U_p^2 + 2r_{10}r_{01}U_pV_p + (1-r_{10}^2)V_p^2 \} \right] + (r_{10}U_p + r_{01}V_p) \exp \left[-\frac{1}{2}(U_p^2 + V_p^2) \right] \times \sqrt{\frac{\pi}{2}} \left(1 + \operatorname{erf} \left(\frac{r_{10}U_p + r_{01}V_p}{\sqrt{A}} \right) \right) \right] \tag{40}$$

Hence, it can be seen that $p(U_p, V_p)$ is determined from only r_{10} and r_{01} . However, γ is necessary to compensate the distortion in the non-dimensionalization. By using the same method as that of Cartwright and Longuet-Higgins (1956), the probability density of the quantities at the time of the maximum water surface elevation can more directly be derived without introducing envelope functions. Through this derivation, Eq. (40) can be obtained without the assumption of a narrow-banded frequency spectrum.

Figure 3 depicts examples of $p(U_p, V_p)$. The probability for U_p to take a negative value decreases as r_{10} increases.

For a symmetrical wave field, in which the principal direction coincides with the mean direction, $r_{01}=0$. Then, Eq. (40) becomes

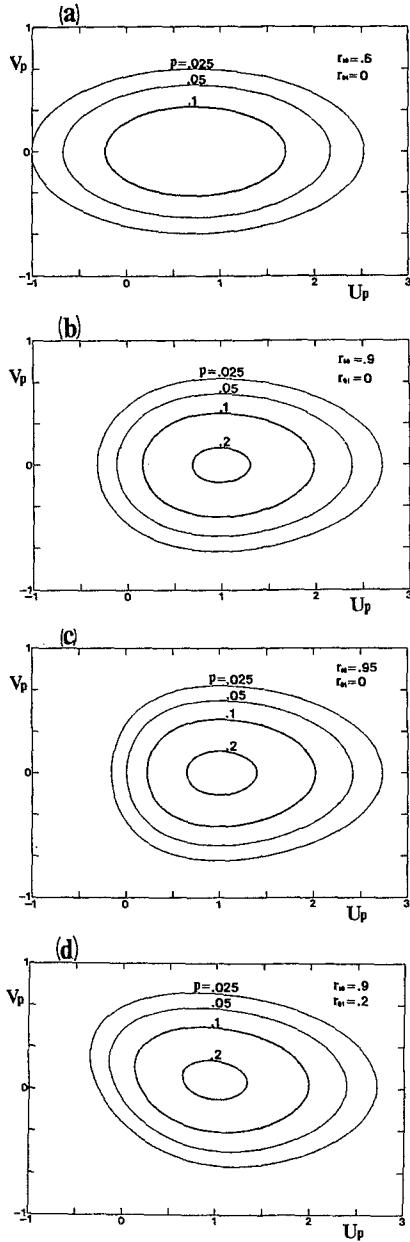

Fig. 3 Joint distribution of the two components of water particle velocity at the time of the maximum water surface elevation.

$$p(U_p, V_p) = \frac{1}{\sqrt{2\pi}} \left[\begin{aligned} &\sqrt{1-r_{10}^2} \exp\left[-\frac{U_p^2}{2(1-r_{10}^2)}\right] \\ &+ r_{10} U_p \exp\left[-\frac{U_p^2}{2}\right] \\ &\times \sqrt{\frac{\pi}{2}} \left(1 + \operatorname{erf}\left(\frac{r_{10} U_p}{\sqrt{1-r_{10}^2}}\right)\right) \end{aligned} \right] \times \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{V_p^2}{2}\right] \quad (41)$$

This indicates that U_p and V_p are independent of each other. The root-mean-square values of these parameters are

$$(U_p)_{\text{rms}} = 1 + r_{10}^2 \quad (42)$$

$$(V_p)_{\text{rms}} = 1 \quad (43)$$

Furthermore, in the limit of $r_{10} \rightarrow 1$, Eq. (41) becomes

$$p(U_p, V_p) = U_p \exp\left[-\frac{U_p^2}{2}\right] \times \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{V_p^2}{2}\right] \quad (44)$$

which shows U_p has a Rayleigh distribution and V_p has a normal distribution. The average magnitude of the water particle velocity for a fixed direction can be calculated as

$$\bar{W}(\alpha) = \int_0^\infty W p(W, \alpha) dW / \int_0^\infty p(W, \alpha) dW \quad (45)$$

With the same assumption that gives Eq. (44), the following explicit expression can be obtained:

$$\bar{W}(\alpha) = 2 \sqrt{\frac{\pi}{2} \left(\cos^2 \alpha + \frac{\sin^2 \alpha}{r^2} \right)} \quad (46)$$

3. FIELD EXPERIMENT

3.1 Procedure

A field experiment was carried out near Oarai Port in Ibaraki prefecture, Japan, on August 28, 1985. The port which is shown in Fig. 4 faces to the Pacific Ocean. The primary purpose of the experiment is to measure the spatial distribution of directional spectra resulted from the diffraction due to an offshore breakwater. A set of an ultrasonic wave gage and an electro-magnetic current meter was used to measure simultaneously the water surface elevation and the two components of horizontal water particle velocity near the bottom, from which the directional spectrum at the measuring location was calculated. Among four sets of instruments used, three are fixed all day at No. 0, 4 and 8 in the figure, and the other one was moved to measure the directional spectra at No. 1, 2, 3, 5, 6 and 7. The sampling interval is 0.5s and the

duration of one record is 17min. 3s. In the figure, the distribution of significant wave heights and principal and mean wave directions is shown. The details of the result are found in Izumiya et al. (1986).

The location No. 0 at which the water depth is about 13m is for measuring the incident wave condition. This is the only location at which the recorded data is long enough to calculate two-dimensional joint distributions. Data for 22 hours, and hence 75 records are available there. Since high-frequency waves generated by fishing boats appeared in the data, a numerical band-pass filter which passes the components with the frequency between 0.056 to 0.19Hz was employed. This makes the band width of the data narrower than that of the incident waves. The average significant wave height and period are 62cm and 9.4s, respectively. The variance coefficients, i.e. the ratios of the standard deviations and average values, are 0.088 and 0.033 for the significant wave height and period, respectively, which allows to regard the wave field as steady. However, to reduce the effect of variation of wave field, the average values for each record are used for normalizing individual wave properties in the record. The total number of waves is 7343, and the average values, γ , r_{10} and r_{01} , for the 75 records are 0.31, 0.95 and 0.00, respectively.

Fig. 4 Observation site.

3.2 Result

Figure 5 compares the predicted and measured joint probability densities of wave height and period. The distance from the origin and the angle from the horizontal axis represent the non-dimensional height and wave direction, respectively. The wave height is non-dimensionalized by the average wave height. Solid and dot lines denote contour lines of the joint density predicted by the present theory. The numbers in a matrix form show the measured values. The values are multiplied by 100. The agreement between the theory and experiment is quite good.

Figure 6 compares the measured and predicted joint probability densities of the two components of horizontal water particle velocity at the time of maximum water surface elevation. As well as in Fig. 5, contour lines represent the theoretical prediction and numbers represent the experimental result. They agree well with each other.

4. CONCLUSION

In the present study, the joint probability density of wave height and direction is derived from the envelope functions of the water surface elevation and the two components of horizontal water particle velocity. In the derivation, the frequency spectrum is assumed to be narrow-banded, and the wave direction of an individual wave is defined similarly to the mean direction. The result is expressed in explicit forms which contain only the long-crestedness parameter and the correlation coefficients between the water surface elevation and the two components of horizontal water particle velocity.

Fig. 5 Comparison between the predicted and measured joint probability densities of wave height and period.

The validity of the present theory is examined by a field experiment. The measured and predicted joint probability densities agree well with each other. Since the numerical band-pass filter used for eliminating ship waves makes the frequency spectrum narrow-banded, the theory remains to be examined for a wide range of sea conditions.

Fig. 6 Comparison between the measured and predicted joint probability densities of the two components of horizontal water particle velocity at the time of the maximum water surface elevation.

CHAPTER 38

FIELD MEASUREMENT OF WAVE SET-UP

By Gregory A. Davis* and Peter Nielsen**

Abstract

A new, efficient and cheap method is described for obtaining field measurements of surf zone mean water levels. The method applies manometer tubes rather than the traditional pressure transducers. Together with simple stilling well measurements of the water table the results obtained from manometer tubes demonstrate for the first time a complete mean water level profile, from offshore of the break-point to the back-beach region.

While some previous studies have provided information about the average position of the waterline, the present study is the first to provide comprehensive field data on the position of the shoreline defined as the intersection of the mean water surface and the sand. The difference between average position of the waterline and the shoreline is not trivial.

1. Introduction

1.1 Concepts and Definitions

When waves break on a beach the water line moves back and forth with the arrival of individual waves. Its instantaneous co-ordinates are x_w and z_w . Correspondingly, the average position of the water line defines \bar{z}_w (see Figure 1).

When the local surface elevation $\eta(x,t)$ is averaged over a time span much longer than the wave and surf beat periods but shorter than the tidal period the result is the local mean water level $\bar{\eta}(x)$ which traces mean water surface MWS.

The still water level SWL is the level of the still water surface (i.e. the sea surface in the hypothetical situation of no waves). For practical purposes, the SWL can be taken as the mean water level at infinite depth: $SWL = \bar{\eta}(\infty)$.

** New South Wales Department of Public Works, Coast and Rivers Branch, 140 Phillip Street, Sydney, Australia 2000

Figure 1: Definition diagram for instantaneous water surface parameters, mean water surface and shore line.

The local setup (and setdown) $B(x)$ is defined as the local super-elevation of the mean water surface above the SWL.

Tides, barometric pressure fluctuations, and changes in wave height cause variations to the mean water surface $\bar{\eta}(x)$ on time scales ranging from a few hours to a few days.

The shoreline and hence the shoreline elevation $z_s (= \bar{\eta}_s)$ and the shoreline setup B_s are defined by the intersection of the mean water surface and the beach.

For the intersection between the still water surface and the beach, we shall use the term Still water shoreline SWS.

Note that the shoreline MWL is in general different from the average runup level.

Field measurements of z_w can be obtained with capacitance runup meters (e.g. Guza and Thornton, 1981) or with down-looking cameras (e.g. Holman and Sallenger 1985), and the amount of field data on z_w is large, while field measurements of $\bar{\eta}$ are virtually non-existent. On the other hand, theoretical models are generally aimed at $\bar{\eta}$ because it is more easily tractable by theory than is \bar{z}_w .

The continuation of the mean water surface landward of the shoreline is the water table, which is the surface where the mean pore water pressure is zero. The local level of the water table $\bar{h}(x)$ is thus the level of the free surface in a suitably responsive stilling well.

There are practical difficulties in measuring mean water levels in the surf and swash zones and until now no detailed field measurements have been made of a wave set up profile. A couple of studies (Guza and Thornton 1981, Holman & Sallenger 1985) reported field measurements of the mean elevation of the water line, but this is different from the set up as defined above.

2. Previous Setup Observations

The phenomenon of super-elevated water level at the shoreline on a natural beach is important for a number of reasons. The run up component is important in determining design set-backs and crest-levels for shoreline structures and vulnerability of shoreline protection and natural dunes. The set up component is important to the dynamics of near-shore currents such as undertow, rip currents and longshore currents arising from longshore variations of wave height.

Holman and Sallenger, (1985) report that the study of wave setup was prompted by the hurricane that hit the East Coast of the USA in 1938. Observations of the hurricane event showed a discrepancy of one metre in shoreline elevation between two nearby locations. One location was the relatively exposed area of Narragansett Pier, where wave energy was dissipated as surf. The other location was the relatively calm waters of Newport. Subsequent model tests by Savage (1957) and Saville (1961) verified the existence of wave set-up.

The earliest field measurement of wave set up are reported by R. Dorrestein (1961). He made field observations of set up at various locations across the surf zone. He set up his experimental apparatus at Fernandina Beach on the Atlantic Coast of Florida. He used a pier extending into the sea from a straight beach on which two tide gauges were installed to give offshore water level. On the beach near the shoreline adjacent to the pier, four to six transparent plastic tubes were inserted into the beach to act as stilling wells. The water level in the swash and run up zone could be recorded by filming floats in the plastic tubes.

The experimental method is flawed, however, because the data sampling period of 72 secs is not long enough to average out the effects of surf beat.

Guza and Thornton (1981) used a combination of offshore pressure transducers and a runup gauge in the swash zone to gain information about the shape of the mean water surface. There are two main difficulties with their approach. Firstly, the average position of the water line which is measured by the runup gauge is not related in a simple way to the shoreline setup (Guza and Thornton assumed they were identical) and the absolute levels of the offshore pressure sensors had to be inferred because surveying was impossible.

Holman and Sallenger (1985) applied a similar approach to that of Guza and Thornton, only the resistance runup gauge was replaced by down-looking cameras. Again the average position of the water line was misinterpreted as being equal to the shoreline position.

The present approach differs from the latter two in that the measured quantity is the mean water level and from these measurements the shoreline is found directly as the intersection between the MWS and the beach. Also, the manometer tubes have the great practical advantage over pressure transducers that the elevation of the seaward ends need not be known.

3. Field Measurements

3.1 Field Site

Field measurements of wave set-up were performed at Dee Why beach, an open coastal beach located about 5 km north of Sydney, New South Wales, Australia. The beach faces the south east which is the dominant direction of the swell from the Tasman Sea (see Figure 2).

Figure 2: Location diagram for the field site at Dee Why Beach, Sydney, Australia.

The sand grain size varies somewhat across the profile, being coarsest in the swash zone. A sample taken on 17th November 1987 from the swash zone had the following size characteristics: $d_{50} = 0.30\text{mm}$; $d_{10} = 0.13\text{mm}$; $d_{90} = 0.95\text{mm}$.

Topographically, the beach varies between a rip current topography, with rip spacings of a few hundred metres under high energy conditions, and a steep reflective topography with regular beach cusps after extended periods of calm weather.

A sample of surveyed beach profiles are shown in Figure 3 which shows that the profile envelope corresponding to the field data is quite wide.

Offshore wave height data was provided by two Waverider Buoys, one located in deep water offshore of Botany Bay, 20 km to the south and one directly offshore from the field site.

Tide level data was provided by the Fort Denison Tide Gauge, located inside Sydney Harbour.

Figure 3: Selected surveys of the line along which the mean water level measurements were made. The setup data was collected between December 1986, and September 1987.

3.2 Field Equipment

The basis of the success of the method described here is the use of simple and reliable equipment. In essence, hydrostatic pressure at different points across the surf zone was "translated" through rigid plastic tubes to a central array of riser tubes. The plastic tubes "damped" the response of the system in such a way as to effectively filter out individual waves and surf-beat, leaving the mean water surface over a period of a few minutes (this process being further enhanced by taking a number of observations over a couple of minutes and averaging them).

The equipment comprising the offshore water level "sensors" consists of a stabilising steel chain, and a bundle of plastic tubes of different lengths, deployed permanently (in this case for over one year) across the surf zone. The longest rigid plastic tube extended 204 metres seaward of the bench mark, which is a stilling well positioned close to the average shoreline (see Figure 4).

Figure 4: The "barometer" mounted on the stilling well which served as a bench mark for the surveys for reference it can be compared with the schematic representation in Figure 5.

In order to roughly maintain the same damping effect within the array of tubes of differing length, the inner diameter of the longer tubes was chosen to be 6mm while the shorter ones were 4mm. In hindsight these dimensions must be said to have been well chosen, except perhaps for the longest tube, which ought to have had an i.d. of 8mm in order to obtain optimal response characteristics.

Figure 5: Schematic diagram of the apparatus used for measuring water table levels and hence, setup.

Deployment of the tubes had to be undertaken with some care to ensure no damage occurred to the tubes. All tension was taken by the steel chain, not the plastic tubes.

The tubes, once deployed, were left permanently on site. It is important that the tubes are permanently submerged so that any air bubbles in the system dissolve over time. Air bubbles would contaminate the readings of the system by offsetting the water levels in the riser tubes.

It is also important that the tubes are firmly anchored or buried in the sand so that movements (acceleration) of the tubes are avoided. Such movements would otherwise generate oscillations of the riser tube water levels.

All the tubes were laid out on the beach and bundled together with electrical cable ties. The bundle in turn was tied to a long length of 6mm steel chain. The steel chain was about 10m longer than the longest tube and had a large steel mass attached to the seaward end to help in anchoring. The landward end was fixed to a steel well in the swash zone. This steel well was permanently on site. It was about 300mm o.d., with 6mm thick walls.

The seaward ends of the plastic tubes were covered by geotechnical filter cloth, in order to prevent the intrusion of sand. The landward ends were capped and stowed inside the steel well.

The whole length (some 200m) of bundled up plastic tubes and steel chain was then man-handled out to waist-deep water, and from there a powerful boat dragged the seaward end of the chain out shore-normal from the beach until it was straight and then dropped it. Needless to say, reasonably calm seas and low tide were necessary for this operation.

A few days after deployment, the tubes and the steel chain had been covered by sand and only occasionally did sections of the tubes become exposed due to local erosion.

At the shoreward end, at the steel well in the swash zone, was mounted the "barometer box" (see Figure 4). This heavy steel box was fixed sturdily to the beach well on the day of an experiment at low tide. The permanently deployed plastic tubes had their shoreward ends uncapped and each was connected to the bottom of a vertical glass riser tube, i.d. 22mm, mounted in the barometer box.

The glass tubes were closed to the atmosphere and in turn inter-connected at their tops, so that the air pressures inside were at all times identical (see Figure 5).

An extra glass tube was connected to a reservoir bottle (about 2 litre capacity) partially filled with water to known (surveyed) level, open to the atmosphere, to provide an absolute reference level.

3.3 Experimental Procedure

The system is partially evacuated by sucking by mouth on a vent tube in the riser tube array. This is in order to bring the water levels in the tubes up above the sand to a level where they can be observed. Dye was introduced into the riser tubes to enhance contrast in the photographic observations.

After an initial settling down period of about 20 minutes, recordings were made every half hour throughout a half-tidal cycle, generally starting at low tide and finishing at high tide. With tidal ranges of up to 1.9m and the profile not being linear, this led to considerable variation in the effective beach profile through each field day.

Recordings were made by photographing the vertical glass tubes and the rulers on either side of them, 3 to 5 times with a 20 to 30 second interval, in order to average out traces of surf beat. A "data-back" camera was used so that accurate time was logged with each photograph.

Actual measurements were made by reading the slides off a micro-fiche reader, and adjusting the observed levels in the riser tubes by the absolute water level in the reservoir.

3.4 Water Table Measurements

Water table heights were measured in a series of simple stilling wells installed at four to eight metre intervals along the test traverse of Dee Why Beach.

The wells consisted of plastic pipes of 2.5 to 5 centimetre i.d., capped at the bottom end with geotechnical filter cloth to prevent the intrusion of sand.

The bottom of each well was sunk to a few tens of centimetres below the lowest position of the water table, and the well tops were surveyed.

Measurements of the water levels in the wells were made every half hour with a Geotechnical Instruments "Dip Meter". This is essentially a measuring tape with a conductivity sensor at the end, enabling measurements of the distance between well top and water surface to the nearest centimetre.

The "Dip Meter" measurements were aimed at the details of the water table shape between the shoreline and the runup limit, and the region immediately shoreward thereof. Complementary long term measurements were obtained with a MACE datalogger recording from a Druck pressure sensor inside the permanent stilling well, about 27 metres landward of the average shoreline. Pressure readings were taken every ten minutes for a period of four weeks.

The main purpose of these measurements was to obtain quantitative information about the influence through runup infiltration, of incoming wave height on the average water table height.

4. Study Results

4.1 Setup Profiles

Figure 6 shows a time series of measurements taken at twenty second intervals over about four minutes. A surf beat crest is visible in the readings from the two shortest tubes (3m and 7m) at time 90 seconds. The suppression of the reservoir tube at the same time is also forced by the surf beat. The standard deviations are 2.0 centimetres for the reservoir tube and 0.7 centimetres for the most dynamic offshore tube leading to a combined standard deviation of at most, 2.7 centimetres.

Figure 6: A time series of water level readings at 8 stations taken on 3rd June 1987. Numbers on the curves indicate the distance offshore of the open end. The two shortest tubes show a surf beat peak at $t=90s$, and correspondingly, the reservoir tube is suppressed at the same time.

A total of 120 setup profiles from 11 field days were obtained during the present study.

As an example, a sequence of setup profiles measured on 8th September 1987 are shown in Figure 7.

Figure 7: A series of setup profiles measured at Dee Why Beach on 8th September 1987. The offshore RMS wave height (H_{Orms}) ranged from 0.69 to 0.82 metres during these tests.

All the data from one field day (4th August 1987) are shown in Figure 8. The setup is plotted in dimensionless form (B/H_{Orms}) versus the likewise dimensionless total depth $(D+B)/H_{Orms}$. For comparison, the predicted setup according to Bowen et al (1968), with $\lambda = 0.5$, is also shown.

The setup at the still water shoreline B_{SWS} can be found from the intersection of the line "D=0" with the data. We see that B_{SWS} corresponds rather closely to the predicted value, while the setup is less than predicted seaward of SWSL and much larger than predicted between SWSL and the shoreline. The smaller values at the seaward end can at least partly be explained by wave height variability. For a more detailed discussion see Nielsen et al (1988).

The measured shape of the mean water surface between the still water line and the shoreline shows clearly that the simple model of Bowen et al (1968) does not apply in this area. This was foreseen by Bowen et al.

Quantitatively the data show that (within the data range) the shoreline setup was approximately 40% of the offshore wave height, which is about twice the predicted value from Bowen et al's model with reasonable choices of the wave height to depth ratio.

The data of the present study (reported in full by Nielsen et al, 1988) provide a considerable amount of information, which could serve as a guide line for the development of new models.

Figure 8: Dimensionless setup versus dimensionless total depth. Measurements from 4th August 1987.

4.2 Water-Table Profiles

The results of the integrated study shows that the input of a sinusoidal tide leads to a water table wave which is considerably skewed and on average, super-elevated above the mean shoreline level. This skewing and super-elevation originate mainly from the asymmetry (or non-linearity) of the boundary condition at the shoreline. A simple analytical model for this process is presented by Nielsen et al (1988).

Apart from the tidal fluctuations, the water table will move in response to wave height changes. The effects of these changes on the water table are twofold; firstly, the setup of the shoreline and secondly, a contribution to infiltration from runoff. The nature of this interaction is discussed in detail by Nielsen et al, 1988.

5. Merits and Further Potential of the Method

The main advantages of the method are as follows:-

- No need to level offshore components. The surf is a very harsh environment in which to work. Once the gear is deployed, no surveying of "sensors" is required.
- The equipment is simple and robust. Even in the high wave-energy environment of Dec Why Beach, the gear performed without major fault for over one year, surviving numerous storm events.
- No electronic components. Delicate calibrations and considerations of "drift" not required.
- Low cost. All of the components are readily available and inexpensive.

Further application of the method would be in studies of hydraulic behaviour of river entrances, and also in the study of the behaviour of rips on coastal beaches. A further application may be to study the phenomenon of surf-beat.

Possible improvements to the system may include the following:-

- Instead of using the relatively thin rigid plastic tubes to provide an (uncontrolled) damping of the response of the system, it may be better to deploy larger i.d. tubes and add the capacity to dampen response (by a "choke" mechanism, say) at the manometer box. In this way, all the tubes may be "calibrated" to have similar response characteristics.

The benefits of this may be a better ability to observe water level phenomena that vary within shorter or longer time scales, say for example surf beat instead of wave set-up.

- Use more than one line of tubes to provide a three-dimensional observation of water levels in the surf zone. This would enable the study of rips and rip feeder currents.

6. Conclusion

Manometer tubes of lengths up to two hundred metres have been applied successfully for measuring mean water levels in highly dynamic surf zones. The obtained accuracy was of the order ± 3 centimetres, but to obtain such accuracy it is essential that the tubes are permanently deployed with most of the length kept below the average water level. Then air bubbles will tend to dissolve with time and partial burying of the tubes in the sand will prevent movements due to waves and currents. Such movements could otherwise cause disturbing oscillations of the manometer water surface levels.

The technique has enabled the collection of a unique data base on wave setup and it has great potential for direct measurement of the water level gradients which drive rip currents and rip feeder currents.

CHAPTER 39

On the maximum runup of cnoidal waves.

Costas Emmanuel Synolakis †, A.M., ASCE and Manas Kumar Deb ‡.

This is a study of the maximum runup of cnoidal waves on plane beaches. An approximate theory is described for determining the maximum runup of non-breaking cnoidal waves. It is shown that the linear and nonlinear theory predict mathematically identical maximum runup heights. An asymptotic result is derived for the maximum runup of solitary waves, which are one limiting form of cnoidal waves. A series of laboratory experiments is described to support the theory. Other numerical results are presented that suggest that the runup of cnoidal waves is significantly higher than the runup of monochromatic waves with the same waveheight and wavelength. Preliminary laboratory data are also presented which suggest that, for certain cnoidal waves, the maximum runup is not a monotonically varying function of the normalized wavelength.

1. Introduction

The problem of determining the runup and reflection of cnoidal waves on plane beaches usually arises in the study of the coastal effects of tsunamis. Tsunamis are long water waves of small steepness generated by impulsive geophysical events on the ocean floor or at the coastline. Cnoidal waves are believed to model important aspects of the coastal effects of tsunamis well.

The process of long wave generation and propagation is now well understood. The process of long wave runup and reflection is not. However, there is consensus that one suitable physical model for this process is the formalism of a long wave propagating over constant depth and encountering a sloping beach. The studies of long wave runup have concentrated either on solitary waves or on monochromatic waves, i.e., at the two extremes of cnoidal waves. (For a comprehensive review of studies on solitary wave runup see Synolakis (1986).) To date, there appear to have been only three studies on cnoidal wave runup, one unpublished study by Pedersen and Gjevik (1983), the study of Ohyama (1987) – in Japanese – and the study of Synolakis et al (1988).

† Assistant Professor, School of Engineering, University of Southern California, Los Angeles, California 90089-0242

‡ Graduate Research Assistant, School of Engineering, University of Southern California, Los Angeles, California 90089-0242

Despite the quality of the analytical work, fundamental unresolved questions about the runup of long waves still persist. For example, in the study of solitary waves, the empirical relationship between the normalized runup and the normalized wave height that has been established in the classic laboratory investigations of Hall and Watts (1955) remained, until recently, unexplained. The results of the available numerical solutions have not been confirmed with detailed surface profiles from laboratory data, and, as a consequence, there is little conclusive information about the relative importance of dispersion and nonlinearity during runup. Until Synolakis (1987), there was no realization of the differences in the runup behaviour of breaking and nonbreaking long waves, and this had led to comparisons between numerical data for nonbreaking waves with laboratory data for breaking waves. There is still little understanding of the criteria that determine whether a wave breaks during runup or rundown, or of the reflection process. Compared to recent advances in understanding periodic wave runup on natural beaches, (Huntley et al 1977, Guza and Thornton, 1982 and Holman, 1986) the state of the art in cnoidal runup has been very limiting.

In the present study an exact solution to an approximate theory is described for determining the runup of long waves up plane beaches. The basic solution details and the evolution of the amplitude for solitary waves have been presented in Synolakis (1987). Some results for cnoidal waves have been presented in Synolakis et al (1988). In this paper we will summarize the predictions of the linear and nonlinear theory and we will show that the linear and nonlinear theory predict mathematically identical maximum runup heights. We will summarize the asymptotic results that lead to the runup law presented *ibid* and we will present numerical results for the runup of cnoidal waves. These results hint on a rich and unexpected behavior in the runup of long waves.

2. Basic equations and solutions

Consider a topography consisting of a plane sloping beach of angle β , as shown in figure 1. The origin of the coordinate system is at the initial position of the shoreline and x increases seaward. The topography $\tilde{h}_0(\tilde{x})$ is described as follows :

$$\tilde{h}_0(\tilde{x}) = \tilde{x} \tan \beta \text{ when } \tilde{x} \leq d \cot \beta \text{ and } \tilde{h}_0(\tilde{x}) = d \text{ when } \tilde{x} > d \cot \beta. \quad (1)$$

d is the undisturbed water depth in the constant depth region. Dimensionless variables are introduced as follows : $\tilde{x} = xd$, $\tilde{H} = Hd$, $\tilde{\eta} = \eta d$, $\tilde{h}_0 = h_0 d$, $\tilde{u} = u\sqrt{gd}$, and $\tilde{t} = t\sqrt{d/g}$. Consider a propagation problem described by the shallow water wave equations:

$$h_t + (hu)_x = 0, \quad (2a)$$

$$u_t + uu_x + \eta_x = 0, \quad (2b)$$

where $h(x) = h_0(x) + \eta(x, t)$.

2.1 Linear theory

The system of equations (2) can be linearized by retaining the first order terms only, resulting into $\eta_{tt} - (\eta_x h_0)_x = 0$. When $h_0(x) = x \tan \beta$, a well known solution of this equation is $\eta(x, t) = B(k, \beta) J_0(2k\sqrt{x \cot \beta}) e^{-ikct}$, where B is the amplification factor, k is the wavenumber and $c = 1$. Keller and Keller (1964) presented another steady state solution for the combined topography defined by (1). For an incident wave of the form $\eta(x, t) = A_i e^{-i(x+ct)}$, they determined the amplification factor $B(k, \beta, A_i) = 2e^{-ik \cot \beta} A_i / [J_0(2k \cot \beta) - iJ_1(2k \cot \beta)]$.

Since the governing equation is linear and homogenous, any standing wave solutions can be used to obtain travelling wave solutions by linear superposition. For example, when the incident wave is of the form $\eta(X_0, t) = \int_{-\infty}^{\infty} \Phi(k) e^{-ikct} dk$, then the wave transmitted to the beach is given by :

$$\eta(x, t) = 2 \int_{-\infty}^{\infty} \Phi(k) \frac{J_0(2k\sqrt{xX_0}) e^{-ik(X_0+ct)}}{J_0(2kX_0) - iJ_1(2kX_0)} dk, \tag{3}$$

where $X_0 = \cot \beta$. This solution is only valid when $x \geq 0$. To obtain the details of the solution when $x < 0$ one must solve the nonlinear set (2).

2.2 Nonlinear theory

To solve the nonlinear set (2) for the sloping beach case, $h_0(x) = x \tan \beta$, Carrier and Greenspan (1958) introduced the following hodograph transformation,

$$x = \cot \beta \left(\frac{\sigma^2}{16} - \frac{\psi_\lambda}{4} + \frac{u^2}{2} \right), \quad t = \cot \beta \left(\frac{\psi_\sigma}{\sigma} - \frac{\lambda}{2} \right)$$

$$u = \frac{\psi_\sigma}{\sigma}, \quad \text{and} \quad \eta = \frac{\psi_\lambda}{4} - \frac{u^2}{2}. \tag{4}$$

This change of variables reduces the set of equations (2) to a single linear equation,

$$(\sigma \psi_\sigma)_\sigma = \sigma \psi_{\lambda\lambda}. \tag{5}$$

The transformation is such that in the hodograph plane, i.e., the (σ, λ) space, the shoreline is always at $\sigma = 0$; this can be deduced easily by setting $\sigma = 0$ in (4); then $x = -\eta \cot \beta$, which is an equality only valid at the shoreline tip.

Equation (5) can be solved with standard methods. Defining the Fourier transform of $\psi(\sigma, \lambda)$ as $\Psi(\sigma, \tilde{k}) = \int_{-\infty}^{\infty} \psi(\sigma, \lambda) e^{-i\lambda \tilde{k}} d\lambda$, and, if $\Psi(\sigma_0, \tilde{k}) = F(\tilde{k})$, then the bounded solution at $\sigma = 0$ and $\sigma = \infty$ takes the form :

$$\psi(\sigma, \lambda) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\tilde{k}) \frac{J_0(\tilde{k}\sigma)}{J_0(\tilde{k}\sigma_0)} e^{i\tilde{k}\lambda} d\tilde{k}. \tag{6a}$$

If an initial condition is available instead, one may use Hankel transform methods (Carrier (1966)).

The process of specifying explicitly an initial or a boundary condition to equation (5) is nontrivial. Even if initial or a boundary data are available in the (x, t) space, the process of deriving the equivalent conditions in the (σ, λ) space is very complex. These difficulties have restricted the use of the Carrier and Greenspan formalism and this is rather unfortunate, because some of the problems described can be circumvented. (Carrier, 1966.) Another method has been described by Synolakis (1986, 1987) to specify a boundary condition *including reflection*. We will summarize it here.

2.3 Approximate solution of the nonlinear theory

Carrier (1966) pointed out that far from the shoreline nonlinear effects are small. The transformation equations can then be simplified by neglecting terms $\sim O(u^2)$. To the same order, $\psi_\lambda \ll \frac{\sigma^2}{16}$ and $\frac{\psi_\sigma}{\sigma} \ll \frac{\lambda}{2}$. Using these approximations the transformation equations (4) reduce to $u = \frac{\psi_\sigma}{\sigma}$, $\eta = \frac{\psi_\lambda}{4}$, $x = \frac{\sigma^2}{16} \cot \beta$ and $t = -\frac{\lambda}{2} \cot \beta$. These equations are uncoupled and allow direct transition from the (σ, λ) space to the (x, t) space.

One method for specifying a boundary condition in the physical space is to use the solution of the equivalent linear problem, as given by equation (3), at the seaward boundary, where $x = X_0 = \cot \beta$, i.e., the point $\sigma = \sigma_0 = 4$ in the (σ, λ) space. Then equations (4) imply that $\eta(X_0, t) = \frac{1}{4} \psi_\lambda(4, \lambda)$. The boundary condition $F(\vec{k})$ in the (σ, λ) space is determined from (3) by repeated application of the Fourier integral theorem. Assuming that $\psi(\sigma_0, \lambda) \rightarrow 0$ as $\lambda \rightarrow \pm\infty$, then the solution of equation (5) follows,

$$\psi(\sigma, \lambda) = -\frac{16i}{X_0} \int_{-\infty}^{\infty} \frac{\Phi(\kappa)}{\kappa} \frac{J_0\left(\frac{\sigma\kappa X_0}{2}\right) e^{-i\kappa X_0(1-\frac{\lambda}{2})}}{J_0(2\kappa X_0) - iJ_1(2\kappa X_0)} d\kappa. \quad (6b)$$

3. Comparison of the linear and of the nonlinear theory

The maximum runup according to the linear theory is the maximum value attained by the wave amplitude at the initial position of the shoreline, i.e., at $x = 0$, or

$$\eta(0, t) = 2 \int_{-\infty}^{\infty} \frac{\Phi(k) e^{-ik(X_0+ct)}}{J_0(2kX_0) - iJ_1(2kX_0)} dk. \quad (7)$$

In the nonlinear theory the maximum runup is given by the maximum value of the amplitude at the shoreline $\eta(x_s, \lambda)$. (x_s is the x -coordinate of the shoreline and it corresponds to $\sigma = 0$.) Using (4), one obtains that :

$$\eta(x_s, t) = \frac{\psi_\lambda}{4} - \frac{u_s^2}{2} = 2 \int_{-\infty}^{\infty} \frac{\Phi(\kappa) e^{-i\kappa X_0(1-\frac{\lambda}{2})}}{J_0(2\kappa X_0) - iJ_1(2\kappa X_0)} d\kappa - \frac{u_s^2}{2}; \quad (8)$$

$u_s = dx_s/dt$ is the velocity of the shoreline tip. At the point of maximum runup u_s becomes zero. Setting $u_s = 0$ and $\sigma = 0$ in the transformation equations (4) reduces the transformation equations to $u = 0$, $\eta = \frac{\psi_\lambda}{4}$, $x = -\eta \cot \beta$, and $t = -\frac{\lambda}{2} \cot \beta$. Substitution of these values in equation (8) reduces it to equation (7), proving that the maximum runup predicted by the linear theory is identical to the maximum runup predicted by the nonlinear theory. At the minimum rundown point the shoreline tip attains zero velocity also, and the same argument applies again. This result was first noted by Carrier (1971) in a problem where reflection was negligible. As shown by Synolakis (1987) it is valid in general, even when reflection is important. It is largely unexpected, because the linear and nonlinear theory differ most at the initial position of the shoreline.

4. The cnoidal wave solutions

Cnoidal waves are exact periodic solutions of the KdV equation $\eta_t + (1 + \frac{3}{2}\eta)\eta_x + \frac{1}{6}\eta_{xxx} = 0$. A cnoidal wave propagating over constant depth is given by Svendsen (1974) as

$$\eta(x, t) = y_t - 1 + H \operatorname{cn}^2(2K(\frac{x}{L} + \frac{t}{T})|m). \tag{9}$$

y_t is the distance of the trough from the bottom, and H, L and T are the dimensionless wave height, wavelength and period respectively. $K(m)$ is the first elliptic integral and m is the elliptic parameter. If one defines the Ursell number as $U = HL^2$, then $U = (16/3)mK^2$. The function $\operatorname{cn}(z|m)$ is the Jacobian elliptic function and it is given by Abramowitz and Stegun (1972) as:

$$\operatorname{cn}(z|m) = \frac{2\pi}{\sqrt{m}K} \sum_{i=0}^{\infty} \frac{q^{i+\frac{1}{2}}}{1+q^{2i+1}} \cos[(2n+1)\frac{\pi z}{2K}]$$

$q = e^{-\pi K'/K}$, and K and K' are the real and imaginary quarter periods of the elliptic functions respectively. Cnoidal waves have two important limiting cases. As $m \rightarrow 1$, it can be shown that

$$\eta(x, t) = H \operatorname{sech}^2 \sqrt{\frac{3}{4}H}(x + ct). \tag{10}$$

$c = \sqrt{1+H}$ is the wave celerity. Equation (10) is the Boussinesq profile for a solitary wave. As $m \rightarrow 0$, then

$$\eta(x, t) = \frac{H}{2} \cos 2\pi(\frac{x}{L} + \frac{t}{T}),$$

the profile of a monochromatic periodic wave. For comparison, figure 1 shows a cnoidal wave, a solitary wave and a sinusoidal wave with the same normalized height H propagating over constant depth. The cnoidal and sinusoidal waves also have the same wavelength L .

Figure 1 The amplitude profile of a solitary wave ($\eta = H\text{sech}^2\theta$), a sinusoidal wave ($\eta = \frac{H}{2} \cos \theta$) and a cnoidal wave ($\eta = y_t - 1 + H\text{cn}^2(2K\theta|m)$) with the same $H = 0.027$ propagating over constant depth as a function of the dimensionless phase θ . The cnoidal wave and the sinusoidal wave also have the same wavelength L .

The results of the previous section will now be applied to derive a result for the maximum runup of cnoidal waves climbing up a sloping beach.

4.1 The solitary wave solution

A solitary wave centered at $x = X_1$ at $t = 0$ has the following surface profile $\eta(x, 0) = \frac{H}{d} \text{sech}^2\gamma(x - X_1)$, where $\gamma = \sqrt{3H/4d}$. The function $\Phi(k)$ associated with this profile is derived in the appendix. It is given by $\Phi(k) = (2/3)k\text{cosech}(\alpha k)e^{ikX_1}$ where $\alpha = \pi/2\gamma$. Substituting $\Phi(k)$ into equation (7) and defining as $R(t)$ the dimensionless surface elevation at the initial position of the shoreline, then

$$R(t) = \frac{4}{3} \int_{-\infty}^{\infty} k\text{cosech}(\alpha k) \frac{e^{ik(X_1 - X_0 - ct)}}{J_0(2kX_0) - iJ_1(2kX_0)} dk. \tag{11}$$

This integral can be calculated with standard methods of applied mathematics; its convergence and evaluation is discussed in Synolakis (1987,1988). The integration result is :

$$R(t) = 8H \sum_{n=1}^{\infty} \frac{(-1)^{n+1} n e^{-2\gamma(X_1 - X_0 - ct)n}}{I_0(4\gamma X_0 n) + I_1(4\gamma X_0 n)}. \tag{12}$$

The series can be simplified further by using the asymptotic form for large arguments of the modified Bessel functions. When $4X_0\gamma \gg 1$, then :

$$R(t) = 8\sqrt{\pi X_0} H (3H)^{\frac{1}{4}} \sum_{n=1}^{\infty} (-1)^{n+1} n^{\frac{3}{2}} e^{-2\gamma(X_1 + X_0 - ct)n}. \tag{13}$$

This form of the solution is particularly helpful for calculating the maximum runup. The series in (12) is of the form $\sum_{n=1}^{\infty} (-1)^{n+1} n^{3/2} \chi^n$; its maximum value occurs at $\chi = 0.481$. This value defines the time $t_{max} = (1/c)[X_1 - X_0 - 0.366/\gamma]$ when the wave reaches its maximum runup, and the value of the series at t_{max} is $s_{max} = 0.15173$. Defining as \mathbf{R} the maximum value of $R(t)$ and evaluating the term $8\sqrt{\pi\sqrt{3}s_{max}}$, then the following expression results for the maximum runup :

$$\mathbf{R} = 2.831\sqrt{\cot\beta}(H)^{\frac{5}{4}}. \tag{14}$$

The term *the runup law* has been coined for this equation. It is formally valid when the series converges and when $4X_0\gamma \gg 1$, i.e., $\sqrt{H} \gg 0.288 \tan\beta$.

4.2 Validity of the solution

The solution described is valid for functions $\Phi(k)$ such that the Jacobian of the transformation (4) is never equal to zero. The Jacobian becomes zero when the surface slope $\partial\eta/\partial x$ becomes infinite. In the physical plane this point is usually interpreted as the point of wave breaking.

The Jacobian of the Carrier and Greenspan transformation is $\mathbf{J} = c(t_\sigma^2 - t_\lambda^2)$. Taking the limit as $\sigma \rightarrow 0$, then $\mathbf{J} \rightarrow (u_\lambda - \frac{1}{2})^2$. Using the formalism used in calculating the runup integral (Eq. 11), one can show analytically that the limiting H when $u_\lambda - \frac{1}{2}$ goes through zero, as :

$$H = 0.8183(\cot\beta)^{-\frac{10}{3}}. \tag{15a}$$

This is a weaker restriction than that presented in Pedersen and Gjevik (1983), who reported that waves break when

$$H > 0.479(\cot\beta)^{-\frac{10}{3}}. \tag{15b}$$

However, there are two basic differences between the two results. The Gjevik and Pedersen criterion (15) indicates the limiting H when a solitary wave breaks during the backwash. Equation (15b) indicates when a wave first breaks during runup. Also, the Gjevik and Pedersen result (15b) was derived by using the sinusoidal wave profile that best fits the Boussinesq profile, while equation (15a) is based on the actual Boussinesq profile (Eq. 10).

4.3 Maximum runup

Although it has long been known that breaking and nonbreaking periodic waves follow different runup variations, this behaviour has never been recognized in single-wave runup. In Synolakis (1987), data was presented that demonstrated conclusively that two different runup regimes exist, one for breaking and one for non-breaking solitary waves.

Figure 2a. A definition sketch for solitary wave runup.

Figure 2b. The normalized runup R of solitary waves of height H climbing up different beaches of slope $1 : \cot \beta$ plotted against the runup law (Eq. 13). All data refer to nonbreaking waves and they were derived in the laboratory. The data for the slopes $1 : 11.47, 1 : 5.67, 1 : 3.73, 1 : 2.14,$ and $1 : 1.00$ are from Hall and Watts (1953), the data for the $1 : 2.75$ slope are from Pedersen and Gjevnik (1983), and the data for the $1 : 19.85$ slope are from Synolakis (1987).

To verify this observation for other beaches, the runup law has been compared *ibid* with laboratory data. Comparisons of analytical results with laboratory data such as those of Hall and Watts (1953) are not as straightforward as often assumed. That study includes both breaking and nonbreaking wave data without identifying them as such, and therefore the empirical relationships derived there may not be directly applicable when determining the runup of nonbreaking waves. To perform a posteriori identification of the Hall and Watts data, the breaking criterion (Eq 15) was used, and the identified nonbreaking wave data are presented in figure 2b. The abscissa is the runup law (Eq. 14), and the ordinate is the maximum runup. The asymptotic result does appear to model the laboratory data very well. No data are presented for slopes smaller than 1:20, because no such data are yet available; on a 1:100 slope, the highest nonbreaking wave is a wave with $H \approx 0.003$.

4.4 The cnoidal wave solution

Consider an incoming cnoidal wave of the form (9). In this case the method of choice for the solution is a Fourier–Bessel series. The solution proceeds in a manner similar to the development in section 4.2.

The complete expression for a cnoidal wave is given by

$$\begin{aligned} \eta(x, t) = & y_t - 1 \\ & + \frac{2\pi^2 H}{mK^2} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \frac{q^{i+j+1}}{(1+q^{2i+1})(1+q^{2j+1})} \cos 2\pi(i+j+1)\left(\frac{x}{L} - \frac{t}{T}\right) \\ & + \frac{2\pi^2 H}{MK^2} \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \frac{q^{m+n+1}}{(1+q^{2n+1})(1+q^{2m+1})} \cos 2\pi(m-n)\left(\frac{x}{L} - \frac{t}{T}\right). \end{aligned} \quad (16)$$

Using the Keller and Keller (1964), and, after some algebra, we obtain the wave transmitted to the beach and eventually the wave amplitude at the initial shoreline :

$$\begin{aligned} \eta(0, t) = & y_t - 1 \tag{17} \\ & + \frac{4\pi^2 H}{mK^2} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \frac{q^{i+j+1}}{(1+q^{2i+1})(1+q^{2j+1})} \frac{\cos[\phi - k_{ij}(\cot \beta + c_0 t)]}{\sqrt{J_0^2(2k_{ij} \cot \beta) + J_1^2(2k_{ij} \cot \beta)}} \\ & + \frac{4\pi^2 H}{mK^2} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \frac{q^{i+j+1}}{(1+q^{2i+1})(1+q^{2j+1})} \frac{\cos[\phi' - k'_{ij}(\cot \beta + c_0 t)]}{\sqrt{J_0^2(2k'_{ij} \cot \beta) + J_1^2(2k'_{ij} \cot \beta)}}. \end{aligned}$$

$k_{ij} = 2\pi(i+j+1)/L$, $k'_{ij} = 2\pi(i-j)/L$, $\phi = \arctan[\frac{J_1(2k_{ij} \cot \beta)}{J_0(2k_{ij} \cot \beta)}]$ and $\phi' = \arctan[\frac{J_1(2k'_{ij} \cot \beta)}{J_0(2k'_{ij} \cot \beta)}]$. Since $\cot \beta \geq 1$, the arguments of the Bessel functions are either zero or much larger than one, and the Bessel functions can be replaced by

their asymptotic forms for large arguments. Simplifying (17) we obtain,

$$\begin{aligned} \eta(0, t) \approx y_t - 1 &+ \frac{4\pi^2 H}{mK^2} \sqrt{\frac{2\pi}{L} \cot \beta} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \frac{\sqrt{(i+j+1)} q^{i+j+1}}{(1+q^{2i+1})(1+q^{2j+1})} \cos\left[\frac{2\pi}{L}(i+j+1)(\cot \beta - c_0 t) - \frac{\pi}{4}\right] \\ &+ \frac{4\pi^2 H}{mK^2} \sqrt{\frac{2\pi}{L} \cot \beta} \sum_{\substack{i=0 \\ i \neq j}}^{\infty} \sum_{j=0}^{\infty} \frac{\sqrt{|i-j|} q^{i+j+1}}{(1+q^{2i+1})(1+q^{2j+1})} \cos\left[\frac{2\pi}{L}(i-j)(\cot \beta - c_0 t) - \frac{\pi}{4}\right] \\ &+ \frac{2\pi^2 H}{mK^2} \sum_{i=0}^{\infty} \frac{q^{2i+1}}{(1+q^{2i+1})^2}. \end{aligned} \quad (18)$$

As $m \rightarrow 0$, it is possible to simplify this expression. However, since it is necessary to determine the behavior $\forall m$, we proceed with a direct evaluation of the series in Eq (18).

Figure 3 shows the maximum relative runup of cnoidal waves R/H with the same H as a function of the dimensionless wavelength L up three different sloping beaches. The figure suggests that the runup of a cnoidal wave is substantially higher than the runup of the monochromatic wave with the same height and wavelength. It is also seen that there exists a minimum in the functional variation of the cnoidal wave runup with the wavelength. This minimum is more pronounced in the runup variation of the larger waves, in Figures 3(b) and 3(c).

All the waves in figure 3 are nonbreaking. The linear theory cannot provide directly a breaking criterion. To determine when waves start to break, the Jacobian of the Carrier and Greenspan transformation was monitored continuously as described in Synolakis (1986). The implication is that these results are valid for waves climbing up very steep beaches or for very long waves. Most natural beaches are gently sloping, and it is not obvious if similar differences exist. However, Figure 3 does suggest that the common practice of choosing the dominant frequency of an incoming wave-spectrum and using the runup of the monochromatic wave with that dominant frequency for calculating wave runup may not be entirely appropriate when the incoming wave energy is dominated by low frequency swell.

To investigate if this behavior can be demonstrated in the laboratory, a series of preliminary experiments were conducted in the 40m wave tank of the Keck Laboratory of Hydraulics and Water Resources of the California Institute of Technology. At a distance of 20m from the wave generator a sloping beach of 45° angle was installed. The wave generation system and the generation algorithm is described in detail by Skjelbreia (1987).

The results of the laboratory experiments for the climb of cnoidal waves of $H = 0.1$ up a 45° beach are shown in Figure 3. The relative runup is shown to decrease and then increase again as the wavelength increases. This is as the theory suggests.

Figure 3 The maximum relative runup of sinusoidal waves (dashed lines) and the maximum relative runup of cnoidal waves (solid lines) with the same height H up three sloping beaches as a function of the dimensionless wavelength. (a) $H = 0.027, \beta = 5.7^\circ$; (b) $H = 0.05, \beta = 11.3^\circ$; (c) $H = 0.1, \beta = 45^\circ$. Nonbreaking waves.

Figure 4. The maximum relative runup of nonbreaking cnoidal waves with $H = 0.1$ up a 45° beach as a function of the normalized wavelength. Laboratory data after Synolakis et al (1988).

This behavior is not entirely unexpected. The current paradigm in wave runup predicts that the relative runup decreases as the wave-steepness decreases, i.e., as the wavelength increases Ahrens and Titus (1985). On the other hand, there is empirical evidence (ibid) that as the nonlinearity of a given wave increases, the relative runup increases as the wavelength increases. (This is an intuitively pleasing behavior for cnoidal waves; as the nonlinearity increases and the wave has an increasing portion of its volume above the mean water level, the relative runup is expected to increase.) Figure 3(c) and Figure 4 suggest that both descriptions are correct, over different ranges of the wavelength.

We suggest two explanations why this behavior has been previously unrecognized. One, most existing runup data have been obtained from laboratory studies with monochromatic waves, where the effects of nonlinearity are difficult to quantify. Two, since most empirical runup relationships are based on synthesis of laboratory data from many different runup investigations, it is likely that any anomalies in the functional variations were attributed to differences in the quality of the data.

5. Conclusions

In summary, our analysis suggests the following conclusions.

1) The runup of nonbreaking waves predicted by nonlinear theory is mathematically identical to the runup predicted by linear theory for waves climbing up plane beaches.

2. The runup of solitary waves is described well by the runup law,

$$R = 2.831\sqrt{\cot\beta(H)}^{\frac{5}{4}}.$$

3. Different criteria apply for wave breaking during runup and rundown.

4. The runup of cnoidal waves is significantly higher than the runup of the equivalent monochromatic waves.

5. The runup variation of cnoidal waves is not a monotonically increasing or decreasing function of the wave steepness.

CHAPTER 40

THE WAMS MODEL APPLIED TO THE MEDITERRANEAN SEA

Luigi Cavaleri*, Luciana Bertotti*,
Jose E. De Luis** and Piero Lionello*

Summary

The application of an advanced third generation wave model to the Mediterranean Sea is described. The model is based on the physical description of the wind wave evolution, avoiding any shortcoming in the estimate of the single terms that contribute to the energy budget. The capability of the model to respond to any meteorological situation is illustrated by applying it to a severe storm occurred in January 1987. The results show that the crucial point for the final accuracy lies in the correct evaluation of the wind field.

Introduction

The SWAMP study (SWAMP, 1985), intercomparing the results of ten different wave models for some well defined tests, made clear that, for any drastic improvement in the field to arise, a completely new approach to the problem was to be taken. In particular any shortcoming in the description of the wind wave evolution had to be released, and the problem had to be

- * Istituto per lo Studio della Dinamica delle Grandi Masse, C.N.R., San Polo 1364, 30125 Venice, Italy.

approached only on a physical basis. Being beyond the capability of any single group, the task was faced by a whole team of modellers. The result is the so-called "third generation WAM wave model" (WAMDI-Group, 1988).

While most of the WAM group interest was in the large oceans, we have focused our attention on the Mediterranean Sea. This is a quite interesting basin, with a rather complicated meteorology. Occasional very heavy storms are present, which, from the point of view of a modeller aiming at a detailed study, have the advantage of being free of any distant swell eventually affecting the local results. In the following sections we give a brief description of the model, of its implementation in the basin, and we discuss the implications of the results.

The WAM Model

The WAM model, or WAMS, in its shallow water version used for the Mediterranean Sea, is based on the numerical integration of the energy balance equation. It is assumed that wave conditions at a given time t and location ϕ and λ (ϕ = latitude, λ = longitude) are represented by the two-dimensional spectrum $F(f, \theta, \phi, \lambda, t)$, f and θ being the frequency and direction that characterize the single wave component. The evolution of $F()$ on the spherical earth is governed by the transport equation

$$(1) \quad \frac{\partial F}{\partial t} + (\cos \phi)^{-1} \frac{\partial}{\partial \phi} (\dot{\phi} \cos \phi F) + \frac{\partial}{\partial \lambda} (\dot{\lambda} F) + \frac{\partial}{\partial \theta} (\dot{\theta} F) = S$$

where S represents the local source function and the dots represent derivatives with respect to time.

Specifically

$$(2) \quad \dot{\phi} = v R^{-1} \cos \theta$$

$$(3) \quad \lambda = v \sin \theta (R \omega \sin \phi)^{-1}$$

$$(4) \quad \dot{\theta} = v \sin \theta \tan \phi R^{-1}$$

Here v is the group velocity and R is the radius of the earth.

The left side of the energy balance equation represents the kinematics of wind waves, i.e. the advection, and its solution is purely a mathematical problem. The physics of waves, the dynamics of the problem, is on the right side term S that is considered as composed of three parts

$$(5) \quad S = S_{in} + S_{nl} + (S_{br} + S_{bf})_{dis}$$

S_{in} represents the input of energy from the wind based on the Miles process,

$$S_{in} = \beta F$$

where the expression for β is adopted from Snyder et al. (1981). With respect to the original expression the model uses a slightly modified version of β based on the friction velocity U_* . It is given by Komen et al. (1984) as

$$(6) \quad \beta = \max \left(0, 0.25 \frac{\rho_a}{\rho_w} \left(2.8 \frac{U_*}{c} \cos \theta_w - 1 \right) \right) \cdot \sigma$$

($\sigma = 2\pi f$, ρ_a , ρ_w = air and water density, c = water

phase velocity, Θ_w = angle between wind and wave direction).

S_{nl} represents the nonlinear conservative energy exchanges between all the possible quadruplets of wave components that satisfy given resonance conditions. Requiring enormous computer power for its evaluation, the evaluation of S_{nl} has been brought within the actual operational capabilities by the discrete interaction operator parametrization proposed by Hasselmann et al. (1985).

The accuracy of the procedure has been proved by direct comparison against the full calculation results done for different spectral shapes. In shallow water the nonlinear exchanges are corrected by a scaling factor evaluated according to Harterich and Hasselmann (1980). The involved approximation is within acceptably small limits in the range $kd > 0.8$ (k is wave number, d is depth).

S_{dis} represents the dissipation processes, and it can be conveniently split into whitecapping and bottom interaction processes. Whitecapping or breaking is the only relevant dissipation term in deep water. For its evaluation the model uses a modified version of the expression proposed by Komen et al. (1984) given as

$$(7) \quad S_{br}^d = -2.35 \cdot 10^{-5} \tilde{\omega} \left(\frac{\omega}{\tilde{\omega}} \right)^2 \left(\frac{\tilde{\alpha}}{\tilde{\alpha}_{PM}} \right)^2 F$$

The tilde represents a slight approximation to the exact values as, for stability reasons, mean circular frequency $\tilde{\omega}$ is obtained as the inverse of the mean period. Specifically

$$(8) \quad \tilde{\omega} = E \omega^4 / g^2$$

$$(9) \quad \hat{\alpha}_{PM} = 3.02 \cdot 10^{-3}$$

E is the overall energy, g the acceleration of gravity.

The only bottom dissipation process permanently considered in the model is bottom friction. The bottom friction is expressed by

$$(10) \quad S_{bf} = - \frac{\Gamma}{g^2} \frac{\sigma^2}{\sinh^2 kd} F$$

a parametrized expression deduced from the JONSWAP study (Hasselmann et al., 1973, henceforth referred to as J) with the constant $\Gamma = 0.038 \text{ m s}$.

Equation (1) includes the long distance refraction of wave train associated with the great circle path. For shallow water this term, given by (4), is augmented to include the refraction due to the variation of water depth.

In the actual version the model considers 25 frequencies in geometric progression ($f_1 = 0.0418 \text{ hz}$, $f_{n+1} = 1.1 f_n$), and 12 directional bands with 30 degree resolution. Beyond the upper frequency limits ($F_{25} = 0.4114 \text{ hz}$) the spectrum is completed with a f^{-4} tail.

WAM Implementation in the Mediterranean Sea

Two grids, with different resolution, have been used to represent the geometry of the basin, respectively with 0.25 and 0.50 degree resolution. In this paper we describe the former, applied to the western Mediterranean Sea.

The grid is shown in Fig. 1. It covers the area from Gibraltar till Bengasi at the right end of the Sirte Gulf. The 0.25 degree resolution corresponds to

20-24 km in longitude and 28 km in latitude. This is largely enough to describe with good accuracy the geometry of the coasts. Obviously, if detailed studies were to be carried out at a single location, a nested high resolution model should be used. We point out how this implementation requires almost as many points as the global model at the three degree resolution described by the WAMD1-Group (1988).

The advection and integration time steps have both been fixed at 15 minutes. The outputs are available at 3-hour intervals. All these are optional quantities. In the actual form the model requires 5 minutes of CPU on a CRAY X-MP48 for each day of simulation.

Figure 1. Grid covering the western Mediterranean Sea
The resolution is 0.25 degree. Dots indicate
wave recording positions.

Wind Fields

Two main sources of wind fields are available for the Mediterranean Sea, the European Centre for Medium Range Weather Forecasts (ECMWF) and the British

Meteorological Office (BMO). the latter has been used for the hindcast here reported.

The BMO runs a global model within which a high resolution nested model is used to describe in detail the wind over Europe. In this area, and in particular over the Mediterranean Sea, the wind is provided at the knots of a geographic grid with 0.9375 degree resolution in longitude and 0.75 degree for latitude. This corresponds to a step size of 70-80 km. The wind is available at 1-hour intervals, and it is linearly interpolated in longitude and latitude to provide the wind fields in correspondence of the WAM grid. At the same time, prior to the use by the wave model, the wind is transformed into wind stress according to the formula

$$U_*^2 = c_D U^2$$

where c_D is a friction coefficient that is again a function of U given by (WAMDI-Group, 1988)

$$c_D = \max(1.2875, 0.8 + 0.065 U) 10^{-5}$$

Severe Events of 10-15 January 1987

Several major storms have been hindcasted and compared with measured data. The results show in general the very good performance of the WAM model, even in basins with complicated geometry as the Mediterranean Sea. As an example we report here the results for a period of severe events that took place in the first fortnight of January 1987. Between 10 and 15 January two sequential storms entered the western Mediterranean producing heavy sea conditions twice at a short interval. Fig. 2 reports the wave fields (significant wave height H_S , in meters) for 03 and 21 UT of 11 January.

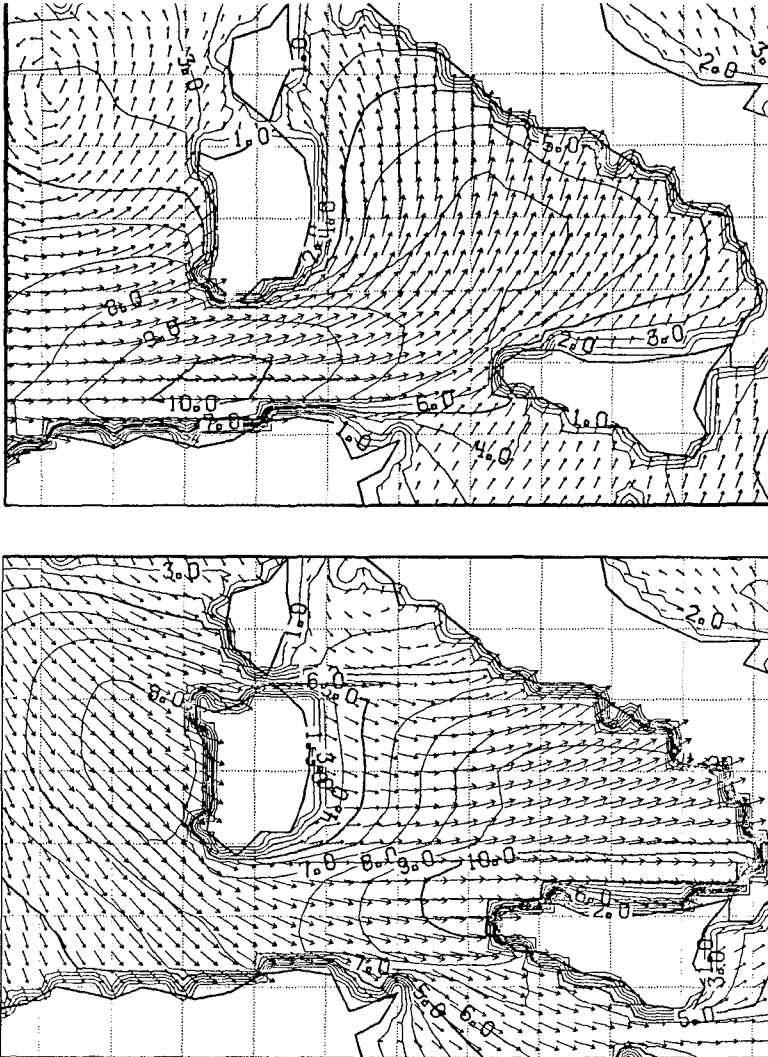

Figure 2. Wave fields for 03 and 21 UT of 11 January 1987.

Several wave measuring stations were active during this period. Anyhow most of them are of little use because of short fetch or secluded locations. The two main sources of information came in this case from Palma de Mallorca, in the Balearic Islands, and Montalto di Castro on the west coast of Italy marked by dots in Fig. 1. At both stations a Waverider buoy was operating, and the records were taken for 20 minutes at 3-hour intervals. Fig. 3 shows the H_s comparison between model and experimental data at Palma for the period 8-15 January. Both the storms are well reproduced, particularly in the growing stage, the decay being anticipated a few hours by the hindcast. This is likely, as from direct inspection of the maps, to be strictly dependent on the input wind fields.

Figure 3. Model results versus experimental data at Palma de Mallorca (see Fig. 1).

Fig. 4 shows four sequential 2-dimensional spectra at Palma out of the model. The arrow in each figure represents the direction of the local and actual wind (the modulus is shown in the lower righthand corner, 1.0 corresponding to about 18 m/s). Ten levels of energy, scaled on the peak value, are shown. The three complete circles are at 0.05, 0.10 and 0.20 hz frequency.

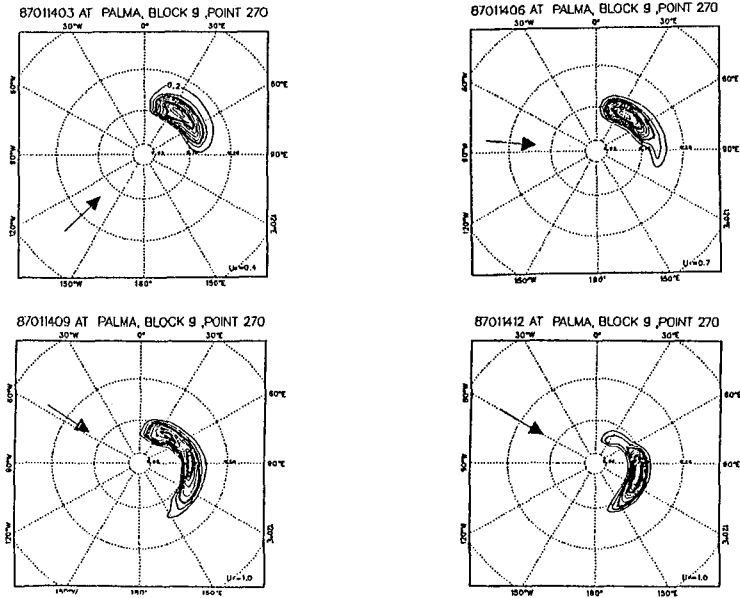

Figure 4. Four sequential 2-dimensional spectra at Palma de Mallorca on 14 January 1987.

The sequence is simultaneous to the passage of the cold front. The wind is firstly from the southwest, ahead of the front, and a well developed 3 meter sea is present in the same direction. While the front is passing (next map of 06 UT) a local wind sea begins to develop in the new wind direction, then quite evident in

the next spectrum of 09 UT. The swell to the northeast is still very strong. A few hours later, at 12 UT, a major storm has developed in the new direction, with H_s up to almost 6 meters, and only a slight swell still propagating to the northeast.

Fig. 5 shows the H_s history at Montalto. On the general trend the storm is well reproduced, but the experimental field showed wild oscillations only partially reproduced in the hindcast. Supported also by evidence of the local wind record, we believe this to be due to oscillations of the wind field largely smoothed by the atmospheric model.

Figure 5. Model results versus experimental data at Montalto di Castro (see Fig. 1).

Conclusion

The main advantage of a physical approach to wind wave description is that the resulting model has no limitation, and it can be reliably applied to any meteorological situation also in basins with very complicated geometry. Together with the ones reported by the WAMDI-Group (1988), the results we have obtained confirm the above statement and the validity of the approach. On the other hand the sensitivity of the results to limited variations of the wind field transfer the problem to the meteorological input. The correct definition of the surface field in the Mediterranean Sea is not an easy task, as proved by detailed tests carried out by Dell'Osso (1984) for the Alpex experiment. It is our feeling that, for the full exploitations of the WAM model capabilities, high resolution local wind models are required to provide correct input in the area of interest.

Acknowledgements

The wave data have been provided for Palma by the Programa de Clima Maritimo, D.G.P. y C., MOPU, Madrid, Spain, and for Montalto by Ente Nazionale Energia Elettrica, ENEL-CRIS, Venice, Italy. We acknowledge their kindness on providing the data.

CHAPTER 41

A NUMERICAL MODEL OF WAVE DEFORMATION IN SURF ZONE

Akira WATANABE* and Mohammad DIBAJNIA**

Abstract

A numerical model is presented for nearshore wave deformation due to shoaling and breaking, and to decay and recovery in the surf zone. The model is based on a set of time-dependent mild slope equations including a term of wave energy dissipation caused by breaking. Its applicability is demonstrated by comparisons between the computations and the measurements of cross-shore distributions of the wave height and potential energy over typical beach configurations.

1. INTRODUCTION

Upon arriving at the nearshore zone, waves come to play an important role in various coastal processes. It is in this area that the waves undergo some drastic changes due to shoaling, diffraction, refraction and breaking, and that they gain the ability to affect sea bottom configuration, to damage man-made structures or to cause difficulties in the handling of ships. A conventional approach to describing nearshore waves is through using the wave energy equation. Although the method has been widely employed in coastal engineering, it is not a general one in the sense that reflection, refraction and diffraction of the waves should be separately calculated. In addition in case of boundaries with complicated geometry, the method faces severe computational difficulties. A more general and new approach is available through using the mild-slope equation first derived by Berkhoff (1972). The equation, expressed in an elliptic form, describes waves under combined diffraction and refraction on a slowly varying bottom. Its solution, however, often involves

* Dr. Eng., Professor, Dept. of Civil Eng., Univ. of Tokyo, Hongo 7, Bunkyo-ku, Tokyo, 113 Japan.

** M. E., Postgraduate student, ditto.

considerable computational trouble, and the treatment of boundary conditions is in general difficult. To overcome these difficulties, simplified parabolic forms of this equation have been derived, which reduce the computation involved, but instead we cannot easily deal with reflected waves in general. Watanabe and Maruyama (1986) have proposed a set of time-dependent mild-slope equations, which has the advantages of reduced computation time as compared with the elliptic form equation and of simpler treatment of boundary conditions for open boundaries as well as for boundaries with arbitrary reflectivity. In addition, their model incorporates wave breaking and decay in the surf zone. However its validity has not yet been fully examined.

The time-dependent mild-slope equations will be applied in the present paper to computing cross-shore change in a one-dimensional wave field; namely, deformation of waves with normal incidence on a straight parallel-contour coast. The selection of such simple conditions will avoid the involvement of wave diffraction and refraction, and enable us to study in details about the wave deformation due to breaking. The formulation for energy dissipation in the previous study will be modified to more properly express the wave decay and recovery processes. Some numerical computations through the new equations will be conducted on cross-shore distributions of the wave height and potential energy over three kinds of typical beach configurations, and compared with the experimental data.

2. Time-Dependent Mild-Slope Equations for Waves in the Surf Zone

Watanabe and Maruyama (1986) have presented a set of the time-dependent mild-slope equations and a numerical model for nearshore waves under combined refraction, diffraction, and breaking. This model is applied here to a cross-shore one-dimensional wave field, and is improved for the behavior in the surf zone.

The equations are expressed in terms of the water surface elevation ζ and the flow rate Q into the cross-shore direction as:

$$\frac{\partial Q}{\partial t} + c^2 \frac{\partial \zeta}{\partial x} + f_D Q = 0 \quad (1)$$

$$\frac{\partial \zeta}{\partial t} + \frac{1}{n} \frac{\partial (nQ)}{\partial x} = 0 \quad (2)$$

where t is time, x is the horizontal coordinate normal to the shoreline, c is the phase velocity, and

$$Q = \int_{-h}^0 u \, dt, \quad n = \frac{1}{2} \left(1 + \frac{2kh}{\sinh 2kh} \right) \quad (3)$$

in which u is the x -component of the orbital velocity, h is the water depth, and k is the wave number. Equations (1) and (2) may be regarded as vertically integrated equations of motion and of continuity, respectively. In Eq. (1), f_D is the energy dissipation factor, and has been expressed by Watanabe and Maruyama (1986) as:

$$f_D = \alpha_D \tan\beta \sqrt{\frac{g}{h} \left(\frac{Q_m}{Q_r} - 1 \right)} \quad (4)$$

where $\tan\beta$ is a representative bottom slope around the breaking point, Q_m is the amplitude of Q , and Q_r is the flow rate amplitude of the broken waves recovered in an area of uniform depth of h and expressed as $Q_r = \gamma' \sqrt{gh^3}$. Values of 2.5 and 0.25 have been proposed by them for the coefficients, α and γ' , respectively. The dissipation factor, f_D , is set equal to zero outside the surf zone and in any region in which $Q_m < Q_r$. Under this condition, $f_D = 0$, Eqs. (1) and (2) reduce to the mild-slope equation proposed by Berkhoff (1972).

In order to improve the behavior of the model for the wave decay and recovery processes, we now redetermine the expression for the energy dissipation factor f_D . A proper modeling of wave transformation in the surf zone depends strongly on appropriate evaluation of this factor. Several models for wave motion in the surf zone have been proposed. A brief summary of the works up to the present is given by Horikawa (1988). However, the wave breaking process and the subsequent breaking-induced turbulence have not yet been fully clarified and much remains to be done. In the present work a semi-empirical general expression for f_D is given through using some new concepts and experimental results.

If we assume purely progressive waves, combination of Eqs. (1) and (2) yield the following wave energy equation.

$$\frac{d}{dx} (E c_g) = -n f_D E \quad (5)$$

where E is the wave energy density per unit horizontal area, and c_g is the group velocity. Now assuming long waves over a uniformly sloping beach and a constant ratio of the wave height to the water depth, we obtain the following expression for f_D from Eq. (5).

$$f_D = \alpha_D \tan\beta \sqrt{\frac{g}{h}} \quad (6)$$

For a general bottom topography, Eq. (6) needs some modification. To do this we should introduce two parameters. The first one is the amplitude of the wave-induced flow rate inside the surf zone of a uniformly sloping beach, which will be denoted by Q_s . According to experimental data (Isobe, 1986), Q_s can be safely formulated as:

$$Q_s = \gamma_s c h, \quad \gamma_s = 0.4 (0.57 + 5.3 \tan\beta) \quad (7)$$

For the second parameter, we will adopt the flow rate of recovered waves in a similar way to Watanabe and Maruyama (1986). Let us assume waves coming into an area of uniform depth h after breaking as shown in Fig. 1. It is well known that upon arriving at this area, broken waves start to recover and after a certain distance shown as the transient zone, they will find a stable form and will no more lose their energy. Considering the experimental results (Maruyama & Shimizu, 1986), the amplitude of the flow rate of recovered waves, Q_r , can be expressed as:

$$Q_r = \gamma_r c h, \quad \gamma_r = 0.4 (a / h)_b \quad (8)$$

where $(a/h)_b$ is the ratio of the wave amplitude to the water depth at the breaking point.

Figure 1 Wave recovery zone with constant depth.

The fact that the value of f_D should become equal to zero for recovered waves suggests that at any water depth, the value of Q_r may be regarded as the critical flow rate below which there is no dissipation of energy. Therefore we assume the following form of expression for f_D .

$$f_D = A (Q_m - Q_r)^m \quad (9)$$

where at any depth Q_m is the amplitude of the actual flow rate and Q_r is the flow rate amplitude of the broken waves virtually recovered in the same constant depth. The power m should be less than unity in order to get a finite distance to recovery. The proportionality constant A can be determined by requiring that when $Q_m = Q_s$

then the value of f_D should be equal to that for uniform slope, i.e. Eq. (4). Assuming $m = 1/2$ for simplicity we finally obtain Eq. (10) for general bottom topography.

$$f_D = \alpha_D \tan \beta \sqrt{\frac{g}{h} \left(\frac{Q_m - Q_r}{Q_r - Q_s} \right)} \quad (10)$$

The location of the breaking point is calculated with the generalized breaker index diagram proposed by Watanabe *et al.* (1984). Change in the mean water elevation is evaluated through the distribution of radiation stresses, which are calculated from time histories of ζ and Q by using the formulas presented by Watanabe and Maruyama (1986).

3. Boundary Conditions

For the computation of a cross-shore one-dimensional wave field, there are two boundaries: the offshore boundary and the shoreline boundary.

The offshore boundary where incident waves are prescribed is treated as an open boundary in order to let the reflected waves, if any, to go out of the region freely. For this, assuming a locally constant depth region at the offshore, we express the boundary condition in terms of the water surface elevation as:

$$\zeta(x_0) = \zeta(x_0 + \Delta x) + a_1 \{ \sin(kx_0 - \sigma t) - \sin[k(x_0 + \Delta x) - \sigma(t - \tau)] \} \quad (11)$$

where $\tau = \Delta x / c_0$, Δx is the grid length in the finite difference scheme, a_1 and σ are the amplitude and angular frequency of the incident waves, respectively, the subscript 0 denotes quantities at the offshore boundary and the x -axis is taken shoreward.

At the shoreline, previous computations have usually assumed a hypothetical constant depth region to avoid infinity in the value of wave height. However, the solution of the time-dependent mild-slope equations gives a time history of wave propagation so that the breaking point can be determined contemporarily with the computation of wave propagation and the wave height will decay thereafter. This makes it possible to impose the shoreline boundary condition simply as $Q = 0$. The receding of the shoreline due to change in the mean water level is also included using a moving boundary technique.

4. Results and Discussion

The nearshore wave model based on Eqs. (1), (2), and (7) to (10) is here applied to computing wave deformation for three kinds of typical beach profiles: uniform slope,

step-type, and bar-type. The equations are solved by a finite difference method with a staggered mesh scheme.

The results are compared with measurements reported by Nagayama (1983) in Figs. 2 to 4, where H is the wave height, E_p is the potential energy, ρ is the water density, and the x -axis is taken here in the offshore direction with the origin at the shoreline in still

Figure 2 Wave height and potential energy on a uniform slope.

Figure 3 Wave height and potential energy on a step-type beach.

water. The potential energy in the measurements has been evaluated from the mean square values of $\zeta(t)$ at each location.

The wave decay, recovery, and secondary breaking are well reproduced in the computations. Although the wave height is slightly underestimated around the breaking

Figure 4 Wave height and potential energy on a bar-type beach.

point as is anticipated whenever linear theories are used, the distributions of the potential energy which represents overall intensity of the wave motion over one wave period are very well estimated. The small disagreement in the potential energy on the step-type beach before the first breaking point is attributed to the generation of cross waves in the wave channel.

Figure 5 shows the cross-shore variations of some other quantities calculated for the case of the bar-type beach. Figure 5(a) gives the variations of the energy dissipation factor f_D and of the energy dissipation rate per unit mass $n f_D E / \rho$. It is seen that after the first breaking the energy dissipation becomes zero as the water depth behind the bar increases and it is kept as zero until the secondary breaking occurs. In Fig. 5(b) the variation of the mean water level is shown. Unfortunately experimental data of the mean water level change are not available. However, considering the results for wave energy, we can expect that the wave set-up/down are well predicted, as we have found in further applications of the model. Figure 5(c) shows the variations of the flow rate amplitude Q_m and Q_r .

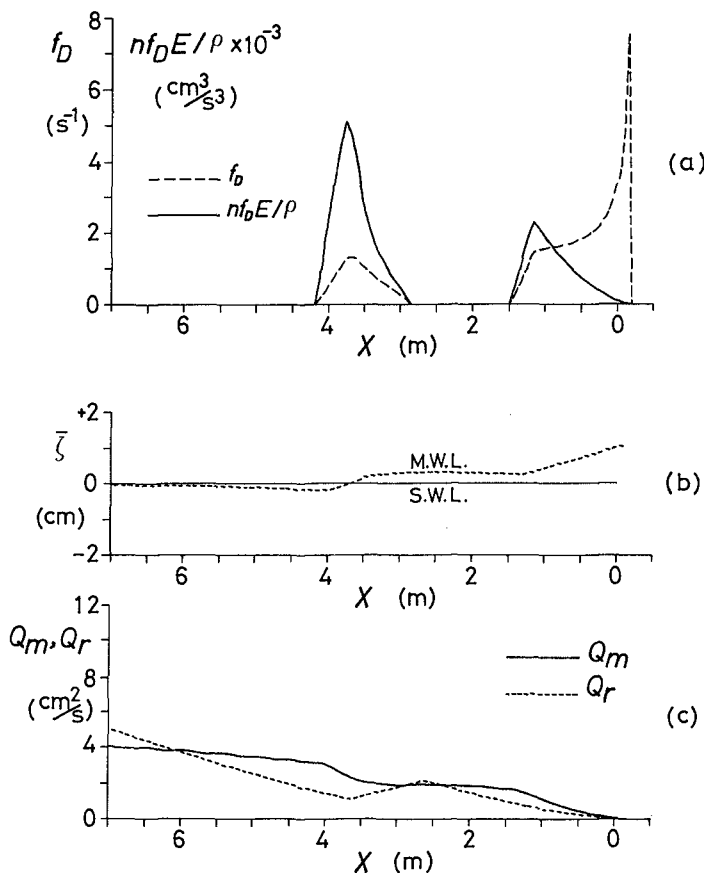

Figure 5 Energy dissipation factor, dissipation rate, mean water level and flow rate amplitude.

5. Concluding Remarks

A numerical model for nearshore waves based on the time-dependent mild-slope equations have been presented, with modification of the term for the energy dissipation due to breaking. It has been shown that the model can reproduce very well cross-shore wave deformation due to shoaling, breaking, decay, and recovery.

Generalization of the present model to two-dimensional wave fields will be rather straightforward and easy to conduct in a similar way to that described by Watanabe and Maruyama (1986). The two-dimensional model thus obtained will be applicable to computing wave deformation due not only to shoaling, breaking and recovery but also to refraction and diffraction.

CHAPTER 42

COUPLING STOKES AND CNOIDAL WAVE THEORIES IN A NONLINEAR REFRACTION MODEL

Thomas A. Hardy¹, A.M. ASCE
Nicholas C. Kraus², M. ASCE

ABSTRACT

An efficient numerical model is presented for calculating the refraction and shoaling of finite-amplitude waves over an irregular sea bottom. The model uses third-order Stokes wave theory in relatively deep water and second-order cnoidal wave theory in relatively shallow water. It can also be run using combinations of lower-order wave theories, including a pure linear wave mode. The problem of the connection of Stokes and cnoidal theories is investigated, and it is found that the use of second-order rather than first-order cnoidal theory greatly reduces the connection discontinuity. Calculations are compared with physical model measurements of the height and direction of waves passing over an elliptical shoal. The finite-amplitude wave model gives better qualitative and quantitative agreement with the measurements than the linear model.

INTRODUCTION

Wave transformation models are commonly used in coastal engineering projects to provide nearshore wave height and direction. This information is needed at specified grid locations for input into nearshore circulation and shoreline change numerical models. Often, multiple simulations over a wide geographical area are required. Small-amplitude (linear) wave theory is the basis for almost all wave transformation models presently in engineering use. It is well known that finite-amplitude (nonlinear) wave theories predict greater shoaling and less refraction than does small-amplitude theory, and the nearshore wave properties predicted by nonlinear theories are expected to provide an improved description of real waves transforming in shallow water. However, the dual requirements of accuracy (finite-amplitude theories) and efficiency (minimal computer CPU time) have been thought to be contradictory. Also, finite-amplitude wave transformation models have proven complicated and difficult to develop.

There are three main challenges in developing a finite-amplitude wave refraction model. First, if computationally intensive, numerically based wave theories are to be avoided, two perturbation theories are necessary, Stokes for deeper water and cnoidal for shallower water. Mutually consistent solutions are essential, and expressions must be available for secondary quantities such as wave energy flux. Second, efficient and accurate calculation of cnoidal wave theory is necessary. Finally, the connection between

(1) Department of Civil and Systems Engineering, James Cook University, Townsville, Queensland, Australia 4811, (2) Senior Research Scientist, Coastal Engineering Research Center, U.S. Army Engineer Waterways Experiment Station, P.O. Box 631, Vicksburg, MS, USA 39180-0631

the two theories has to be optimized. The purpose of this paper is to present a numerical model which accurately and efficiently calculates finite-amplitude wave refraction over an irregular sea bottom. The outputs of the model are wave height and wave direction at each grid node for a steady state monochromatic wave. The model is intended for engineering use where a number of simulations are required and information is desired over a large area of open-ocean coast.

LITERATURE REVIEW

Two of the earlier efforts in the study of finite-amplitude wave transformation treated shoaling of cnoidal waves. Svendsen and Brink-Kjaer (1973) connected first-order cnoidal theory with linear theory to develop a wave shoaling equation. They imposed the requirement of a matching energy flux to connect the two theories. Svendsen and Buhr-Hansen (1977) continued the study of shoaling by altering the connection to allow a discontinuity in energy flux but maintaining a matching wave height between linear theory for deeper water and first-order cnoidal theory for shallower water. The theories were connected at $d/L_0 = 0.1$, where d is depth and L_0 is the linear deepwater wavelength. Cnoidal theory predicted greater shoaling than linear theory and there was good agreement with laboratory measurements of wave height.

The first finite-amplitude refraction model for an irregular bathymetry was presented by Chu (1975). He used a combination of third-order Stokes and first-order cnoidal wave theories. He avoided the need of an expression for energy flux for cnoidal theory by using the flux from the hyperbolic wave theory of Iwagaki (1968) for the calculation of wave shoaling. Ray tracing was used to calculate refraction. The connection between Stokes and cnoidal theories was at a critical Ursell number, U_c , given by

$$U_c = 7.5 + 25\frac{H}{d} \quad (1)$$

where H is wave height. Stokes theory was used if the Ursell number,

$$U = \frac{HL^2}{d^3} \quad (2)$$

was less than U_c and cnoidal theory used if $U > U_c$, where L is wavelength

A finite-amplitude refraction model applicable to straight and parallel bottom contours was developed by Skovgaard and Petersen (1977). The model employed first-order cnoidal theory, and the authors suggested that it should be connected to a linear model if $U > 15$ and $d/L_0 < 0.1$ by matching energy flux at the connection. Headland and Chu (1985) built upon the above-mentioned work of Svendsen and Brink-Kjaer and Svendsen and Buhr-Hansen, to develop a refraction model for nonplane bathymetry using ray tracing techniques. They reported that problems in the connection between linear and first-order cnoidal theories, as well as inefficiencies in the calculation of cnoidal wave properties, required further research. Oh and Grosch (1985) presented a refraction model which was based on third-order Stokes theory and used ray tracing methods. However, they incorrectly applied the model to shallow water, outside the region of validity of Stokes theory (Kraus, Cialone, and Hardy, 1987a).

Dalrymple (1988) presented a model with a solution scheme similar to the one presented in this paper and previous work by the authors (Cialone and Kraus, 1987; Hardy and Kraus, 1987; and Kraus, Cialone, and Hardy, 1987). Wave-current interaction was included, but the use of finite-amplitude theory was inconsistent. Wavelength was calculated using third-order Stokes theory with an empirical correction applied to allow calculation in shallow water. However, the finite-amplitude effect on wave shoaling was incorrectly represented since a mixture of linear and nonlinear theories was used in the calculation of wave energy flux.

NUMERICAL MODEL

The model presented in this paper is based on derivations of third-order Stokes theory and second-order cnoidal theory of Isobe and Kraus (1983a, 1983b). These derivations are consistent in definitions and solution technique; both specify the second definition of Stokes (zero mass flux) to determine the wave celerity.

The model builds on separate refraction models for Stokes waves (Cialone and Kraus, 1987) and cnoidal waves (Hardy and Kraus, 1987). Expressions for energy flux which are necessary for wave height calculations and the basic solution mechanics were developed in these previous efforts. The present model, called NLWAVE for Non-Linear WAVE model, refines a preliminary version (Kraus, Cialone, and Hardy, 1987b) by adopting an improved finite difference scheme and optimizing the connection between the component theories.

The difficulty in the calculation of cnoidal quantities has been a deterrent to the practical application of cnoidal wave theory. Subroutines in computer libraries and formulae found in mathematics handbooks for the calculation of needed elliptic functions cannot be directly used in cnoidal wave theory. The result has often been inefficient and inaccurate calculations. NLWAVE uses the method developed by Isobe (1985) for first-order cnoidal theory and extended to expressions for second-order cnoidal theory by Hardy and Kraus (1987). The procedure allows the efficient and accurate calculation of cnoidal wave properties.

The model uses a compact and direct technique for the calculation of wave refraction, which was introduced for linear waves by Noda *et al.* (1974). This scheme allows the determination of wave properties at predetermined grid locations and thus offers a distinct advantage over wave ray tracing methods which require interpolation to provide information at grid points.

The solution technique can be divided into three parts. First, wavelength is calculated using the dispersion relationship of the appropriate wave theory (third-order Stokes or second-order cnoidal). Second, wave angle is determined using the equation for the irrotationality of wave number, which can be written as

$$\nabla \times \nabla k = 0$$

or

$$\frac{\partial}{\partial x} \left(\frac{\sin \alpha}{L} \right) - \frac{\partial}{\partial y} \left(\frac{\cos \alpha}{L} \right) = 0 \quad (3)$$

where k is wave number, α is wave angle, and the directions x and y are as defined in Figure 1. And third, energy flux, F , and thus wave height, H , are determined from a conservation of energy flux equation given as

$$\nabla \cdot \vec{F} = 0$$

or

$$\frac{\partial}{\partial x} (F \cos \alpha) + \frac{\partial}{\partial y} (F \sin \alpha) = 0 \tag{4}$$

where

$$H \propto \sqrt{F} \tag{5}$$

Energy flux expressions for Stokes and cnoidal wave theories used in NLWAVE were derived in Cialone and Kraus (1987) and Hardy and Kraus (1987) .

Figure 1. Numerical Model Grid

Equations 3 and 4 are solved on a rectilinear grid (Figure 1) using a finite difference scheme. The desired wave properties are functions of wave height, H , wave period, T , and water depth, d . The depth is specified at each grid point and does not change during a simulation. Outer boundary information for H and T is given. This input can either be placed directly at the outer boundary, or deepwater values can be transformed to the outer boundary of the grid assuming straight and parallel bottom contours. The solution scheme marches towards shore (in the $-x$ direction) one row ($i = \text{constant}$) at a time. Each row is swept in the $+y$ direction. Since wave properties are functions of wave height in a finite-amplitude wave theory, iteration is required on each row. The dispersion relationship, the irrotationality of wave number (Equation 3), and the divergence of energy flux equation (Equation 4) are solved for L , α , and F , respectively, using an updated value of wave height. Iteration continues until a convergence criterion defined as a percentage change in the calculated quantity (0.1%) is satisfied. Usually, only two or three and at most six iterations have been found to be necessary .

A simple criterion ($H_b = 0.8d$) is used to determine the height of breaking waves, H_b . Although the model is not intended to describe waves in the surf zone, if depth-limited wave breaking is indicated at a node, then energy flux is reevaluated at the node using the height of the breaking wave. The simulation continues until the wave has broken at all columns across the simulated area.

Equations 3 and 4 can be represented as

$$\frac{\partial A}{\partial x} + \frac{\partial B}{\partial y} = 0 \quad (6)$$

where A and B symbolically represent the quantities in Equations 3 and 4. The finite difference form of Equation 6 is

$$\frac{A_{i,j} - A_{i-1,j}}{\Delta x} + \frac{1}{2\Delta y} \left[(1-a)(B_{i-1,j+1} - B_{i-1,j-1}) + a(B_{i,j+1} - B_{i,j-1}) \right] = 0 \quad (7)$$

where Δx and Δy are the grid spacings, and i and j denote the x and y directions, respectively (Figure 1). A weighting coefficient, a , allows adjustment of the finite difference scheme between explicit and implicit versions. If $a = 0.0$, then the scheme is fully implicit; if $a = 1.0$, it is explicit. A value of $a = 0.5$ is recommended, since this results in the solution with the highest accuracy. This scheme will be labeled ATCS or average time central space, where x is "time like." The ATCS scheme is implicit since it involves unknown values ($j+1, i-1$) as the row ($i-1$) is being calculated (Figure 1). However, the usual penalty of iteration to solve the implicit scheme does not degrade model efficiency since iteration is required for the finite-amplitude solution. Only rarely does the implicit nature of the solution scheme cause an additional iteration, so the difference in execution time between explicit and implicit versions of the model is negligible.

The lateral boundary conditions imposed are the simplest possible; boundary values of α , H , and F are assigned values of their nearest neighboring node on row $i-1$. Tests have shown that the results on the interior of the grid are insensitive to these lateral boundary conditions. However, the lateral boundaries should be placed away from the main areas of interest and not in regions of steep gradients in the bathymetry. A shoreward boundary is not needed as the solution marches towards the shore, and reflections are neglected.

Connection Between Stokes and Cnoidal Components

As has been mentioned previously, neither Stokes nor cnoidal wave theory is valid over the whole range of depths from deep water to the breaking point, and the connection between quantities calculated by the two theories is not always smooth. The range of validity of a particular theory depends somewhat on the derivation of that theory. However, following the review in Kraus, Cialone, and Hardy (1987a), the Ursell number (Equation 2) can be used as a practical validity criterion. In general, Stokes theory is valid for $U < 25$ and cnoidal theory is valid for $U > 10$. Therefore, there is a region of overlap, $10 < U < 25$, where connection between the two theories should be possible.

Since neither third-order Stokes theory nor second-order cnoidal theory is an exact solution to the wave boundary value problem, it is to be expected that the two theories calculate slightly different values of the desired wave parameters (L , α , F) given the same inputs (H , T , d). The differences between the Stokes and cnoidal calculations of

the first two of the parameters, L and α are negligible, as they were found to be less than 1% in numerous tests. However, the differences in calculation of F can be substantial, and this can cause a significant discontinuity in the wave height at the connection node.

Treatment of this problem requires some considerations external to the wave theories. At first thought it might appear best to maintain energy flux across the connection. If the Stokes-determined value of the energy flux is input into the cnoidal calculations of wave height, the resulting wave height is sometimes significantly different from the wave height calculated by Stokes theory. Instead, we chose to follow the lead of Svendsen and Buhr Hansen (1977) and match wave height at the connection. The reasoning is that wave height is a fundamental quantity in the wave theories, whereas energy flux is a secondary or calculated quantity. It is therefore considered more appropriate to maintain the fundamental quantity and allow the energy flux and other secondary quantities to vary. It could be argued that this procedure violates energy conservation. However, repeating from above, neither theory is exact; neither calculates the "true" energy flux. Therefore, we argue that maintaining the primary variables is the most consistent approach and the best way to conserve energy.

At the start of our research into a suitable connection criterion, it was anticipated that it would be a difficult task, perhaps requiring a complex empirical formula to optimize the connection. However, it soon became apparent that the use of second-order cnoidal theory resolved most of the difficulties that previous researchers had encountered using first-order cnoidal theory. To examine the connection, simulations were conducted for a plane beach case. At each of four deepwater wave steepnesses ($H_0/L_0 = 0.005, 0.01, 0.02, 0.03$), four separate connection criteria were tested ($U = 10, 15, 20, 25$). These 16 tests were conducted for the model configured in third-order Stokes/second-order cnoidal mode, as well as in linear/first-order cnoidal mode. At the connection point between the component theories, the percentage change in F was determined as:

$$\% \text{ change} = \frac{F_{\text{cn}} - F_{\text{st}}}{F_{\text{st}}} \quad (8)$$

The subscripts "st" and "cn" denote the Stokes and cnoidal calculated energy fluxes, respectively.

The results presented in Table 1 show a notable improvement for the nonlinear model. In addition, tests using linear/second-order cnoidal and third-order Stokes/first-order cnoidal modes indicated that the improvement in connection was due principally to the use of a higher-order cnoidal theory.

The results in Table 1 indicate that the connection point should be set at $U = 25$, where the discontinuity between energy flux calculated from third-order Stokes and second-order cnoidal theories varies with wave steepness and ranges from -0.25% to -3.7%. In contrast, the difference for the linear/first-order cnoidal combination at $U = 25$ ranges from 8.9% to 24%.

Figure 2 shows the effect of varying the connection criterion. The two curves in this figure correspond to connection at $U = 10$ and $U = 25$ for shoaling on a plane beach using NLWAVE in nonlinear mode, with beach slope of 1/50 and the deepwater wave steepness of 0.03. If the model is switched to second-order cnoidal theory at $U = 10$, the upward trend in wave height that was predicted in deeper water by third-order Stokes theory is reversed. There is a reduction in wave height before resuming the upward trend in much shallower water. However, if the connection is made at $U = 25$, cnoidal theory much more smoothly continues the upward trend in wave height predicted by Stokes theory.

TABLE 1. Percentage Change in Energy Flux at Connection

As a wave begins to be influenced by the bottom as it travels from deep water, there is a slight reduction in wave height due to shoaling before beginning a more rapid increase in height as the water becomes shallower. Stokes wave theory predicts that the region of minimum wave height lies in deeper water, outside the connection region, whereas for cnoidal wave theory, the region of minimum wave height lies inside the connection zone. This phenomenon is clearly visible in Figure 2. Fortunately, the use of second-order cnoidal theory and the selection of the $U = 25$ as the connection criterion greatly reduce the connection discontinuity without the need for empirical corrections.

Figure 2. Connection Comparison. $H_0/L_0 = 0.03$

The adopted connection procedure is as follows: as an iteration is completed at a node on the row $i-1$, the Ursell number is checked against the connection criterion. If $U > 25$ and if the quantities at the node have been calculated using Stokes theory, then the wave height that has been calculated from Stokes theory is used to recalculate L , α , and F using cnoidal theory. These values are then used to carry the solution forward towards the breaker zone. The Ursell number is checked after each iteration for each node on a row and if at a row closer to shore, $U < 25$ at a cnoidal point, then the model switches back to Stokes by using the cnoidal H to calculate a Stokes L , α , and F . The model is designed for application to irregular sea bottoms, so a mixture of Stokes and cnoidal calculation nodes is possible on a row (alongshore). Also, along a column (on-offshore), the scheme can switch from Stokes to cnoidal and back to Stokes as often as is dictated by the bathymetry.

ELLIPTICAL SHOAL TESTS

The cnoidal and Stokes refraction routines performed well in extensive tests with laboratory measurements of wave shoaling and analytical results. These tests have been reported in Cialone and Kraus (1987), Hardy and Kraus (1987), and Kraus, Cialone, and Hardy (1987) and will not be discussed here. In the present paper we examine model prediction by comparing with laboratory measurements of waves focusing over an elliptical shoal.

NLWAVE does not have the capability to model diffractive effects; therefore, it is intended for use in open coast situations where the bathymetry is not complex. As a stringent test of the connection procedure and behavior of the full refraction and shoaling prediction of the model, simulations were conducted for an elliptical shoal. Even though the model is not recommended for application to such bathymetry, it was thought that testing of the model at its limits would be informative. A plan view of the shoal is given in Figure 3. The shoal had a major radius of 13 ft (3.96 m), a minor radius of 10 ft (3.05 m), and a maximum height over the otherwise flat bottom of the basin of 1.0 ft (0.305 m). The water depth was 1.5 ft (0.46 m) in the flat bottom region of the basin.

Figure 3. Plan View of Physical Model Basin

Data from physical model tests over this shoal were made available from the US Army Engineer's Coastal Engineering Research Center (Vincent and Briggs, in press). Two of the physical model tests of monochromatic waves were simulated by both linear and nonlinear versions of NLWAVE. The two tests were as follows:

TEST	H	T
M1I	2.54 in. (6.5 cm)	1.3 s
M2I	1.75 in. (4.4 cm)	1.3 s

The specified wave heights were measured in the flat portion of the basin in front of the shoal. For wave height, results from M1I and M2I are shown in Figure 4 and 5, respectively. The results are for sections parallel to the major axis of the shoal and normal to the initial direction of wave propagation, along $y = 0$ ft (Figures 4a and 5a), and $y = 10$ ft (Figure 4b and 5b).

For the present work, wave directions were measured carefully from photographs of wave crests taken during the physical model tests. Results for test M2I are compared with both linear and nonlinear models along $y = 0$ ft (Figure 6a) and $y = 5$ ft (Figure 6b).

As expected, the numerical results are symmetrical about the centerline of the shoal ($x = 0$ ft). Refraction focused increasing amounts of energy toward the centerline as the wave propagated behind the shoal; therefore, wave heights and wave angles near the centerline increased. The finite-amplitude effect on refraction is clearly evident. Along $y = 0$ ft (Figures 4a, 5a, and 6a), the linear model predicts smaller wave heights and larger wave angles than does the nonlinear model. Here, shoaling dominated, and the nonlinear theories predict greater wave heights due to shoaling. Along $y = 10$ ft (Figures 4b and 5b), the linear model predicts greater wave heights along the centerline. Here, refractive effects dominated, and the greater angle changes predicted by linear theory (Figure 6) concentrated more energy towards the centerline.

(a) $y = 0$ ft

LEGEND

- Finite-amp.
- + Small-amp.
- Measured

(b) $y = 10$ ft

Figure 4. Wave Height, Test M11

There is considerable scatter in the wave heights measured in the physical model tests along $y = 0$ ft (Figures 4a and 5a). This was presumably caused by irregularities in the bottom of the basin, nonuniform wave formation at the generator, or wave reflection from the sides and ends of the basin. The finite-amplitude model shows closer agreement with the physical model results than the small-amplitude model. Closer agreement between numerical and physical models is shown along $y = 10$ ft (Figure 4b and 5b). However, the numerical model results show a greater concentration of energy towards the centerline than do the physical model results. This was expected since the numerical model has no diffractive capability. Wave heights calculated by the finite-amplitude model again show better agreement with the measured wave heights than does the linear model.

Figure 5. Wave Height, Test M2I

Noda *et al.* (1974) showed that the solution technique (irrotationality of wave number, conservation of energy) forming the basis of NLWAVE is equivalent to ray tracing. A model using ray tracing techniques would form a caustic behind the shoal and fail because an infinite wave height would be calculated. The model presented in this paper also fails behind the shoal, but the failure is manifested differently. As energy is diverted from the edge of the shoal and directed towards the middle, a negative energy flux is calculated at a node and the wave height becomes undefined. In linear mode the model fails at $y = 11$ ft, whereas in nonlinear mode it continues until $y = 13$ ft. To allow the model to continue calculation behind the shoal, smoothing was added to the finite difference scheme by replacing $A_{i,j}$ in Equation 7 by a three-point average given by

$$A_{i,j} = w A_{i,j+1} + (1-2w)A_{i,j} + w A_{i,j-1} \tag{9}$$

The smoothing adds dissipation to the finite difference solution and reduces both the rate of angle change and the concentration of energy towards the center of the grid. Although this mimics diffraction, the amount of smoothing needed to approximate the diffractive effects would vary with the bathymetry. With $w = 0.167$, the nonlinear mode did not fail, but the linear mode still failed at $y = 15$ ft. No smoothing was incorporated in the model for the results shown in Figures 4, 5, and 6 ($w = 0$). Simulations over less severe bathymetry do not need smoothing to continue calculations to the breaking zone. For the realistic bathymetry for which the model is intended, it is not anticipated that smoothing will be necessary.

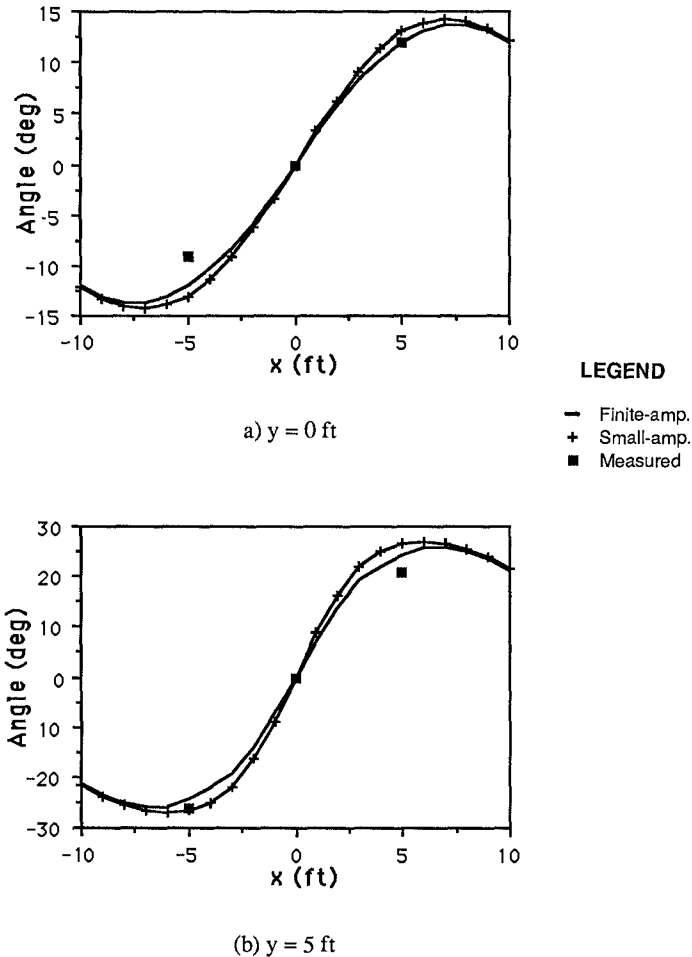

Figure 6. Wave Angle, Test M2I

CONCLUSIONS

A numerical model which efficiently and accurately calculates the shoaling and refraction of finite-amplitude waves over a nonplane bathymetry has been presented. The model can use any combination of Stokes and cnoidal wave theories up to a third-order Stokes and second-order cnoidal combination. The component theories are connected by maintaining wave height at the point of connection. By connecting third-order Stokes and second-order cnoidal wave theories at $U = 25$, the discontinuities which have been reported by previous researchers are minimized. It is concluded that the use of a higher-order cnoidal wave theory is the main factor in the reduction of these discontinuities.

In a test which exercised the model beyond its intended purpose, the numerical solution produced stable and symmetrical results. The nonlinear model provided quantitatively and qualitatively better results than the linear model in reproducing wave height and direction measured in a laboratory experiment.

The difficult and time-consuming work associated with a higher-order refraction model lies in its development. Although the nonlinear model requires approximately 2.5 times as much computer execution time than is required in linear mode, simulation times are small so that the difference can be neglected. On a VAX 750 computer the nonlinear model takes less than three minutes CPU time for a 100 x 100 cell grid.

CHAPTER 43

WAVES IN TURNING WIND FIELDS

G.Ph. van Vledder *) **)

L.H. Holthuijsen *)

Abstract

A numerical model to compute to a high degree of accuracy nonlinear wave-wave interactions of wind generated waves supplemented with formulations of wind generation and white-capping, has been used to estimate qualitatively and quantitatively the effect of these physical processes on the directional response of waves in a turning wind field. After a sudden shift in wind direction the wave spectrum develops a secondary peak in the new wind direction. The initial peak of the spectrum either merges fairly quickly with this new peak or it slowly disappears, depending on the magnitude of the directional wind shift. The turning of the mean wave direction towards the new wind direction is caused by wind generation. The processes of nonlinear wave-wave interactions and white-capping tend to slow down the turning rate induced by the wind generation. The net turning rate of the mean wave direction in the model is twice as slow as in observations acquired in the central and southern North Sea.

Introduction

The directional characteristics of waves at sea are still poorly understood due to the scarcity of observations and the operational problems with wave models that properly represent the physics of waves in a wind field. In both aspects significant developments have taken place in the last few years. Instrumentation to observe wave directions is available on an acceptable operational basis and computers and numerical techniques are now available that permit a limited degree of experiments with the indicated type of wave models.

In the present study the EXACT-NL model of Hasselmann and Hasselmann (1985) is used to quantitatively determine the contributions of generation, dissipation and

**) now at Delft Hydraulics, P.O.Box 152, 8300 AD Emmeloord, the Netherlands.

nonlinear wave-wave interactions to the variation of the mean wave direction in a turning wind field. The results are compared with observations in the North Sea which have been treated to separate the effects just mentioned from the effects of wave propagation.

Numerical computations

The EXACT-NL model is a discrete spectral wave model which has been developed by Hasselmann and Hasselmann (1985) to determine numerically to a high degree of accuracy the rather complicated nonlinear wave-wave interactions formulated by Hasselmann (1968). These computations have been supplemented with formulations from the literature for wind generation and white-capping. For a description of the model reference is made to Hasselmann and Hasselmann (1985) and Van Vledder and Weber (1988). In the EXACT-NL model the evolution of a homogeneous wave field is described by the energy balance equation:

$$\frac{\partial E}{\partial t} = S = S_{in} + S_{ds} + S_{nl} \quad (1)$$

in which E is the two-dimensional variance density spectrum $E(f, \theta)$ and S_{in} , S_{ds} and S_{nl} are the source terms representing the effect of wind input, dissipation by white-capping and nonlinear wave-wave interactions. The model is applied in six situations where a constant, spatially homogeneous wind suddenly turns to a 'new' directions after which the wind direction is constant again. The wind shifts considered are: 30°, 60° and 90° in combination with a constant wind speed U of 10 and 20 m/s. All computations start with a relatively young sea and the waves grow until the peak frequency has dropped to twice the Pierson-Moskowitz frequency at which time the wind direction shifts to the 'new' wind direction.

The mean wave direction θ_0 is defined as in the routine analysis of pitch-and-roll buoys (e.g Kuik et al., 1988):

$$\theta_0 = \arctan \left(\frac{b}{a} \right) \quad (2)$$

in which

$$a = \int_0^{2\pi} \int_0^{\infty} \cos(\theta) E(f, \theta) df d\theta \quad (3)$$

and

$$b = \int_0^{2\pi} \int_0^{\infty} \sin(\theta) E(f, \theta) df d\theta \quad (4)$$

The response of the mean wave direction in turning towards the new wind direction is found to occur in a manner somewhat similar to that of a relaxation process.

Therefore, the rate of change of the mean wave direction is quantified by means of a time scale τ of a relaxation model:

$$\frac{\partial \theta_0}{\partial t} = \frac{1}{\tau} \sin(\theta_w - \theta_0) \quad (5)$$

in which θ_w is the wind direction.

It can be shown by applying the definition operator of mean direction (see equation 2) to the energy balance equation (1), that:

$$\tau = \frac{\cos(\theta_s) \int_0^{2\pi} \int_0^{\infty} \cos(\theta) E(f, \theta) df d\theta}{\cos(\theta_0) \int_0^{2\pi} \int_0^{\infty} \cos(\theta) S(f, \theta) df d\theta} \frac{\sin(\theta_w - \theta_0)}{\sin(\theta_s - \theta_0)} \quad (6)$$

in which θ_s is the mean direction of the total source function $S(f, \theta)$.

The contributions of the above mentioned physical processes to this response are available in the model results as a function of time in the form of spectral source functions. Visual inspection of these provide a qualitative insight in the effect of the various processes. To quantitatively determine the effect of each source term a time scale per source term is introduced in a way similar to that of the time scale of the relaxation model (5), i.e. replace in equation (6) $S(f, \theta)$ by the source term considered. The rationale of this is that upon applying the definition operator of mean direction to the energy balance equation (1), the time scale τ of the relaxation model (5) is related to the time scales per source term as:

$$\frac{1}{\tau} = \frac{1}{\tau_{in}} + \frac{1}{\tau_{ds}} + \frac{1}{\tau_{nl}} \quad (7)$$

The time scales of the response of the mean wave direction (τ) and of the source terms (τ_{in} , τ_{ds} and τ_{nl}) are determined with their definition based on equation (6) from the computed spectra and source functions.

Observations

Observations have been carried out in the central and southern North Sea with a WAVEC pitch-and-roll buoy at two locations near the offshore platforms AUK and K13 (geographic locations 56.39 N, 2.05 E and 53.22 N, 3.22 E respectively). The directional behaviour of the waves in these observations are obviously affected by the inhomogeneity of the wave field. These effects are estimated with the results of an operational hindcast model (the WINCH model, Eide et al., 1986) and the observations are corrected accordingly. The time scales of the response of the mean

wave direction are subsequently determined with a finite difference treatment of the time series of the observed mean wave direction.

To account for effects of measurement errors and to correct for propagation effects, the wave, wind and model data have been selected rather carefully to retain high quality data (e.g. good correspondence between observations and hindcast results). Consequently only five of the fifteen hundred observations were accepted for further analysis.

Results

An example of the response of the two-dimensional spectrum is given in Fig. 1. An example of the various acting and counter-acting energy fluxes (source terms) is given in Fig. 2. The spectrum and the source functions are given for the situation in which the wind shifts suddenly over 90° (constant wind speed of 20 m/s). The illustrated situation is taken half-way through the turning of the wave spectrum towards the new wind direction. The mean wave direction at this moment is 50.3° and the spectrum has developed a secondary peak in the new wind direction (panel a). The wind input source function in this case is located around the new wind direction and turns the spectrum towards this direction (panel b). The dissipation source function is located at the high frequencies while skewed towards the new wind direction thus counteracting (the contribution is negative) the effect of the wind input somewhat (panel c). The nonlinear wave-wave interaction transfers energy from the newly generated high-frequency energy towards the old low-frequency energy in the old direction (panels d and e, for the positive and negative parts of this source function respectively) thus also counteracting the effect of the wind input.

A review of all model results (not shown here) indicates that after a shift in wind direction the wave spectrum always develops a new peak at high frequencies in the new wind direction, resulting in a bi-modal spectrum. However, the spectrum assumes a uni-modal shape rapidly when the wind shift is small or moderate. In a situation with a large wind shift (more than 60 degrees, say) the spectral shape remains bi-modal for a long period of time. In both cases the wind generates energy in the high frequencies in the new wind direction. In the case with a small or moderate wind shift the nonlinear wave-wave interactions siphon part of this new, high-frequency energy away towards lower frequencies in the 'old' wind direction. This, together with the rapid fusion of the two peaks due to their proximity, prevents the continued growth of a distinctly separate high-frequency peak. In the situation with a large wind shift the nonlinear interactions between the high-frequency energy in the new wind direction and the low-frequency energy in the old wind direction is almost nonexistent which provides the high-frequency peak with the opportunity to develop more or less independently from the peak in the old wind direction.

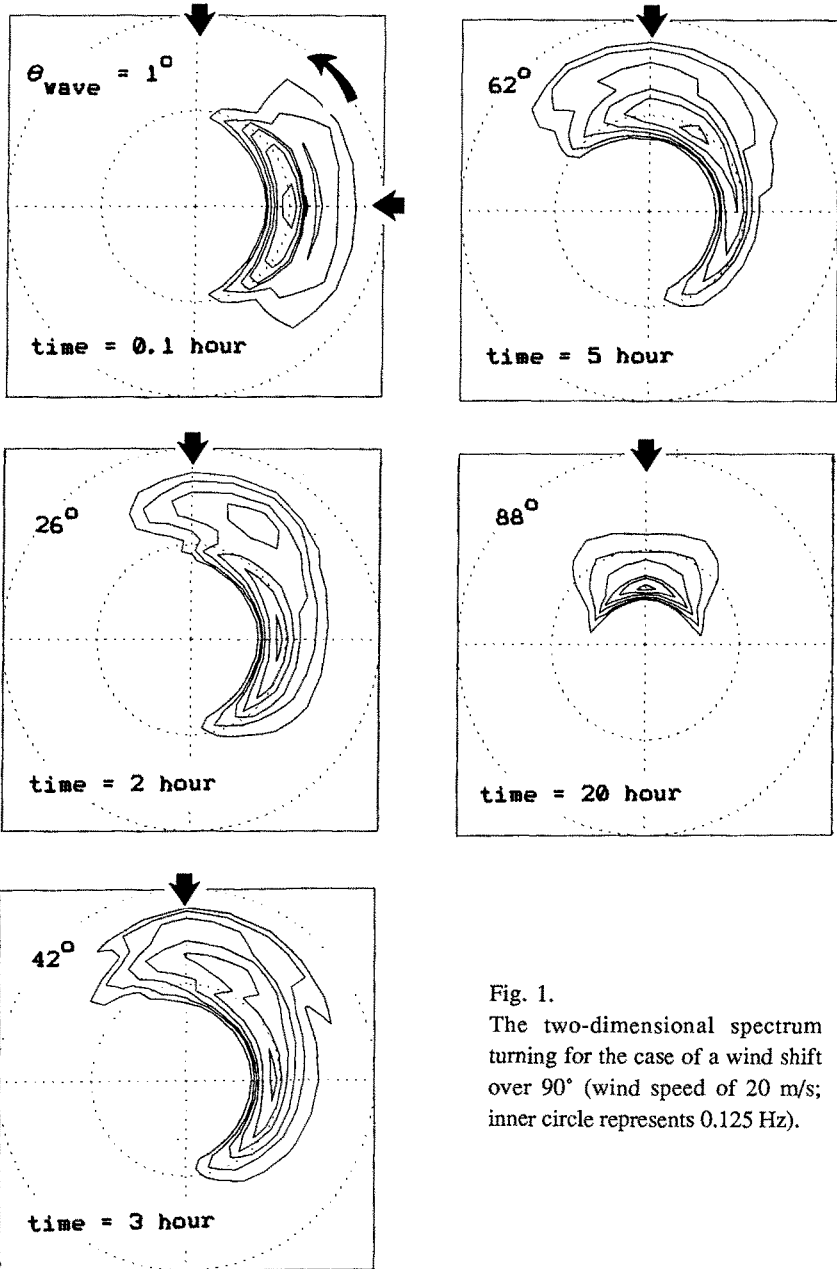

Fig. 1.
 The two-dimensional spectrum turning for the case of a wind shift over 90° (wind speed of 20 m/s; inner circle represents 0.125 Hz).

To generalize the computational results and to compare these results with information from the literature, the time scale estimates are normalized using the friction velocity U_* and the gravitational acceleration g . They are given as a function of growth stage, represented by the nondimensional peak frequency ν_* :

$$\tau_* = \tau g/U_* \quad (8)$$

and

$$\nu_* = f_p U_*/g \quad (9)$$

in which f_p is the peak frequency of the spectrum. Where necessary in the following U_* is determined from the wind speed at 10 m elevation (U_{10}) with the drag coefficient from Wu (1982).

The results of the time scale estimates obtained from the numerical computations and the observations are given in Fig. 3. It appears that the time scale increases with the stage of development of the waves (the response becomes slower as ν_* decreases). A similar increase in time scale is found in the observations. However, the time scales obtained from the observations are about a factor 2 lower than those obtained from the computations. One possible reason for this discrepancy is the severity of the selection of the wave measurements, which perhaps eliminates large time scales.

Comparison with literature

The time scale estimates are compared in Fig. 4 with the results of computations by Young et al. (1987), the results of observations (Hasselmann et al., 1980 and Allender et al., 1983) and with results of Günther et al. (1981) and Holthuijsen et al. (1987) who both parameterized the energy balance equation to estimate the time scales.

The dimensionless time scale τ_* obtained by all these investigators (except Holthuijsen et al., 1987) are only weakly dependent on ν_* , in contrast to the time scales obtained in this study (both the numerical and observational results). The difference between the results of Young et al. (1987) and of the present study (both based on the EXACT-NL model) can be explained by the fact that Young et al. (1987) assumed a constant time scale during the directional response in each case, whereas in the present study the time scale was allowed to vary. The results of Holthuijsen et al. (1987) are generally somewhat closer to those of Young et al. (1987). Holthuijsen et al. (1987) predict the rapid increase in time scale for waves approaching the fully developed stage ($\nu_* = \nu_{*,PM}$).

Relatively large differences occur between the computational results of the present study and the observational results of Hasselmann et al. (1980) and Allender et al. (1983) (as interpreted by Holthuijsen et al., 1987). For the most part ($\nu_* > 0.075$, say), these observed time scales are about a factor 2 to 5 higher than those of the

Fig. 3. Nondimensional time scale estimates τ_* as a function of growth stage ν_* . The results of the computations and observations are indicated with the symbols (x) and (o) respectively. Computations refer to the cases of a sudden wind shift of 30°, 60° and 90° and to the wind speeds $U = 10$ and 20 m/s. The dashed vertical line at $\nu_* = \nu_{*,PM}$ indicates the non-dimensional Pierson-Moskowitz frequency (fully developed waves).

Fig. 4. Time scale estimates obtained from the model computations (x) and from the observations of the present study (o) and time scale estimates in the literature (—).

computations. This difference is possibly due to the nature of the selection procedure followed for these observations. A reanalysis of part of these observations (based on illustrations 7 and 8 in Hasselmann et al., 1980) shows that, when the same selection criteria are used as in the present study (except those related to the hindcast data and not corrected for propagation effects), the remaining observed time scales of Hasselmann et al. (1980) are on the average about a factor 3 lower than the original ones.

Conclusions

Numerical calculations with an advanced wave model (Hasselmann and Hasselmann, 1985) show that the response of the mean direction of waves in a turning wave field is primarily due to the effect of wind generation. This effect is counteracted to some degree by white-capping and nonlinear wave-wave interactions. For comparison with these model results, time scales of directional wave response have been estimated from observations in the southern and central North Sea. Both the model results and the observations indicate that the time scales increase with increasing growth state. However, the observed time scales are a factor of two smaller than the model time scales.

CHAPTER 44

TRANSFORMATION OF SHALLOW WATER WAVE SPECTRA

Genowefa BENDYKOWSKA¹. Gosta WERNER².

ABSTRACT

Investigations are presented on some effects of non-linearity in the motion of shallow water wave spectra. The waves were generated mechanically in a laboratory wave flume with fixed bottom. Essential differences with the linear dispersion relation are found, showing vanishing dispersivity of higher frequency spectral components in strongly nonlinear spectra. The mean frequency increases with decreasing water depth. The relation of the peak frequency to the mean frequency varied in the experiments from 0.9 to 0.5, for deep to shallow water wave spectra respectively.

1. INTRODUCTION

Two following spectral characteristics are analysed

- the dispersion relation of spectral components in shallow water conditions
- changes of the relation between the mean and peak frequencies of wave spectra, propagating over sloping bottom.

The experiments were performed with mechanically generated irregular wave trains, propagating in one direction, over a fixed bed. In these conditions the waves were not affected by the wind and wind generated currents / as it is in laboratory when waves are generated by wind / and did not depend on the angular energy spread nor changes of bottom topography / that always influences the wave motion in field conditions /.

The relationship between the wave number k and the frequency ω , known as the dispersion relation:

$$\omega^2 = gk \tanh kh$$

is widely used and proves a powerful tool in analysing regular wave. However several laboratory/Romamonijariosa 1976, Mitsuyasu et al. 1979 and field Massel, 1980 / measurements on irregular wave trains, show a deviation

 2. Eng. Royal Institute of Technology, S-100 44 Stockholm Sweden

of the dispersion relation from the theoretical one, especially for higher frequencies. Experimental results on wave pressure attenuation Naguszewski et al. 1985 show the same qualitative differences with the commonly used theoretical description, which includes the dispersion relation, given above.

Several theoretical studies have been published, which take into account the influence on the dispersion relation of various aspects of the nonlinearity of a random wave field /Crawford et al. 1981, Huang and Tung 1977, Massel and Chybicki 1983, Masuda et al. 1979 /. All these studies concerned deep water wave conditions.

The results of this study prove an essential departure from the linear dispersion relation of low and high frequency spectral components in a broad range of tested shallow water spectra.

It is often assumed, that for a given wave train, propagating over shallowing water, the peak frequency ω_p and the mean frequency $\bar{\omega}$ do not change with depth and the relation $\omega_p/\bar{\omega} = 0.7 - 0.8$ remains constant through the surf zone / Massel 1980 /. Goda 1987, reports results of a broad statistical analysis of deep water wave trains, simulated according to JONSWAP and WALLOPS spectra, where a strong dependence of $\omega_p/\bar{\omega}$ from the spectral width is proved. Different values of the enhancement factor $\gamma = 1 - 20$ in JONSWAP formula followed changes of $\omega_p/\bar{\omega} = 0.74 - 0.91$; different values of $m = 3 - 20$ in WALLOPS formula gave $\omega_p/\bar{\omega} = 0.58 - 0.95$.

In the following a strong dependence is found of the mean frequency from the relative water depth. These changes follow the changes of the shape (width) of the spectrum and the appearance of secondary peaks at smaller depths.

2. EXPERIMENTS. INPUT SPECTRUM

- Two sets of experiments were performed -
- one - concerned with the measurements of the dispersion relation of spectral components in shallow water wave spectra
 - the second - concerned with measurements of wave spectra over sloping bottom, to study the transformation of spectral parameters on shallowing water depths

The wave flume of dimensions 15 m x 0.305 m x 0.62 m was build of glass. A programmable wave maker of flap type was monitored by a punched tape, read at discrete intervals of 0.02 s. The water surface elevations were measured by means of resistance gauges. Analog records were taken and stored on a tape recorder. The tape recordings were converted into digital data with sampling interval 0.05 - 0.1 s and transmitted to a computer.

In the measurements of the dispersion relation four gauges, spaced equally at 0.1 m, were mounted over the horizontal bottom of the flume. The beach at the end of

Fig. 1 Experimental scheme

the flume was a porous structure of slope 1 : 10. In the second part of the investigations an array of eleven gauges was used: one - over the deep water section and ten at sections of decreasing depth / fig. 1 /.

JONSWAP energy spectrum was generated / of peak enhancement factor $\gamma = 1$ and 6 / consisting of 100 spectral components. The frequency of these components were distributed within cut-off frequencies

$$\omega_{\min} = 0.5 \omega_p \quad , \quad \omega_{\max} = 2.5 \omega_p$$

The frequencies of the spectral components were random values in intervals $\Delta \omega_i = \omega_i - \omega_{i-1}$ determined by the Goda's formula

$$\omega_i = \omega_{i-1} \cdot d \quad , \quad d = \left(\frac{\omega_{\max}}{\omega_1} \right)^{\frac{1}{98}}$$

Phase angles of the components were random within $(0, 2\pi)$

3. DISPERSION RELATION OF THE SPECTRAL COMPONENTS IN SHALLOW WATER WAVE SPECTRA.

3.1 Range of the study.

Usual technique of cross spectral analysis was applied to two simultaneous records, taken at known distances. Wave numbers $k(\omega_i)$ and celerities $C(\omega_i)$ of the spectral components were determined. Only cases of coherence coefficient ≥ 0.8 were analysed. To describe the degree of nonlinearity of the wave spectrum a modified Stokes number was used, as a function of the parameters of the peak spectral component:

$$S = \left(\frac{2\pi}{k_p} \right)^2 \frac{H_s}{h^3} \quad , \quad H_s = 4\sqrt{m_0}$$

The effects of nonlinearity were examined by varying the peak frequency of 7 tested wave spectra in the range: $2.45 \leq \omega_p \leq 7.98$ [rad/s] at two water depths $h = 0.2$ m and 0.4 m. The Stokes' numbers varied between 0.75 and 45.2

3.2 Results

Examples of measured results are given in fig. 2 - 5. On fig. 2 three spectra are shown, measured at water depth 0.2 m

Fig. 2 Energy spectra measured. $h = 0.2$ m

The spectrum of peak frequency $\omega_p = 7.98$ rad/s has a shape very close to that of the input spectrum. The spectrum of the lowest peak frequency $\omega_p = 2.45$ rad/s proves, that the deep water input spectrum transformed in this shallow water conditions into a two-peaks spectrum. The second peak, appearing at $2\omega_p$, is certainly due to bounded waves, that of second order Stokes type.

In fig. 3 some measured results of the wave frequency ω against the wave number k in comparison with the theoretical curve $\omega^2 = gk \tanh kh$ are plotted. All measured results indicate, that the prediction of the linear theory are true only in the vicinity of the peak frequency. The measured curves level out in the bands of $2\omega_p$ and $3\omega_p$. As the tested wave systems were not linear, both free and bounded harmonics existed in the motion. The dominating components are those of the peak frequency, thus also their harmonics travel faster, than free waves of the same frequency. If so, the decrease of the wave numbers of the components $2\omega_p$ and $3\omega_p$ would be explained.

Fig. 3 Comparison of theoretical and measured dispersion relation. $h = 0.2$ m.

In fig. 4 the line $C(\omega)/C_0(\omega) = 1$ is the theoretical relation. All spectral components of $\omega > 1.5 \omega_p$ in all tested cases travel at higher velocities, than the theoretical. The presence of bounded waves is one explanation. Another one is, that in the range $\omega > 2.5 \omega_p$ no free wave components are generated, so only bounded and interaction waves of that frequencies exist in the wave train, both propagating faster than free waves. In the range $\omega < \omega_p$

the measured components phase velocity is either higher / high Stokes' number / or lower / low Stokes' number / than predicts the theory. A similar result was found by Crawford et al, 1981, in their numerical study. The relationship in fig. 5 shows most evidently the influence of the nonlinearity of the motion on the dispersive behaviour of the spectral components. For cases of higher Stokes' numbers the dispersivity of components of $\omega > \omega_p$ vanishes and all these components travel at the velocity of the peak frequency component.

Fig. 4 Measured component phase velocity normalised by its theoretical value. $h = 0.2$ m.

 - ▽ $\omega_p = 4.40$ rad/s, $S = 25$
 - x $\omega_p = 5.34$ rad/s, $S = 9.8$
 - + $\omega_p = 6.74$ rad/s, $S = 6.4$
 - o $\omega_p = 7.98$ rad/s, $S = 3.73$

Fig. 5 Measured component phase velocity normalised by the peak component phase velocity.

4. SPECTRAL CHARACTERISTICS OF WAVE SPECTRA OVER SLOPING BOTTOM.

4.1. Range of the study.

The experiments were performed for four different wave spectra of peak frequencies $\omega_p = 6,25, 7,87$ and $12,56$ while two wave trains of different energies were tested for $\omega_p = 7,87$ rad/s. Wave spectra were measured over two slopes $\gamma = 0,04$ and $0,06$ with $h = 0,4$ m in the deep water section of the flume. The mean frequencies and the width of the spectra were determined from spectral analysis:

$$\bar{\omega}^2 = \frac{m_2}{m_0} , \quad \varepsilon^2 = 1 - \frac{m_2}{m_0 \cdot m_4} , \quad m_n = \int_0^\infty \omega^n S(\omega) d\omega$$

4.2 Results.

Results, concerning the changes of the mean frequency of the spectrum, when propagating from deep water $\bar{\omega}_0$ / over decreasing depth $\bar{\omega}$ / are shown in fig 6. Results, obtained for both tested slopes are plotted together. They prove an increase of the mean frequency when the water depth decreases.

Changes of the relation between the peak ω_p and the mean frequency $\bar{\omega}$ of the spectrum as a function of the relative water depth $k_{p_0} \cdot h$ (k_{p_0} - wave number of the deep water peak frequency component $k_{p_0} = \omega_p^2/g$) are given in fig. 7. The peak frequency didn't change from deep water $/h = 0.4m/$ up to the shallowest water depth $/h = 0.05 m/$, except the case of highest peak frequency tested $/\omega_p = 12.56 \text{ rad/s} /$, when a shift of about 10 % toward the lower frequency band occurred for both tested slopes. The relation $\omega_p/\bar{\omega}$ varies from 0.9 on deep water, to 0.5 for very small relative depth. Those changes are due to the changes of the shape of the spectrum. The values of the spectral width given in table 1 show a consequent increase of ϵ^2 with decreasing water depth. An example of energy spectra measured at different water depth presented on fig. 8, explains, that the

Fig. 6 Changes of mean frequency. Experimental results. $\gamma = 0.04$ and 0.06

Fig. 7 Relation of peak the frequency to the mean frequency. Experimental results. $\gamma = 0.04$ and 0.06 . Legend as on fig. 6

Fig. 8 Changes of energy spectra over sloping bottom $\gamma = 0.06$, $\omega_p = 6.28$ rad/s.

increase of the spectral width is due to the increasing nonlinearity of the wave motion on smaller depth / see fig. 2 for comparison /.

Fig. 9 shows a comparison of the experimental curve with field data measured in the coastal zone of the Black Sea. The measurements were done at six wave conditions, of peak frequencies varying between 0.72 to 1.59 rad/s, at depths 1.5 - 3 m. It should be mentioned, that for the field data the mean frequency was determined as $\bar{\omega} = \frac{2k_p}{T_z}$, where T_z is the average zero-up crossing period.

Table 1. Spectrum width parameter measured in the experiments

slope	ω_{p0} rad/s	ξ^2	
		h = 40 cm	h = 5 cm
0.06	12.56	0.210	0.379
	7.87	0.329	0.403
	7.87	0.393	0.631
	6.28	0.338	0.628
0.04	12.56	0.228	0.403
	7.87	0.382	0.560
	7.87	0.417	0.573
	6.28	0.437	0.639

5. CONCLUDING REMARKS.

- The relative water depth of the peak frequency component $k_p \cdot h$ proves to be good measure of the nonlinearity of a shallow water wave spectrum. Presence of bounded harmonics and waves of interaction between free spectral components are supposed to account for all shallow water effects observed in the experiments.
- An essential departure from the theoretical dispersion relation is proved in the experiments. The spectral components of the peak frequency band follow the relation in all tested cases. Components of frequency $\omega > \omega_p$ propagate faster, than predicted theoretically and for strongly nonlinear wave trains the dispersivity of those components almost vanishes. Components of frequency $\omega < \omega_p$ propagate either slower / moderate nonlinearity / or faster / strong nonlinearity /, than predicts the theory.
- The mean frequency $\bar{\omega}$ increases with decreasing water depth / $k_p \cdot h < 1$ /. The relation between the peak and the mean frequencies decreases with decreasing relative water depth in a range $0.5 < \omega_p / \bar{\omega} < 0.9$.
- The spectral characteristics of the peak frequency components are the most reliable parameters in a simple estimation of a spectrum. The parameter of the mean frequency / zero-crossing period / has a poor physical meaning in shallow water wave spectra.

- The very simple laboratory model, applied in this experiment, proves a good tool in studying general features of shallow water wave spectra. The comparison with other field data and results of different laboratory technics and numerical simulations / Crawford et al. 1981, Goda 1987, Mitsuyasu et al. 1979, Ramamonijarisoa 1976 / gives a satisfactory qualitative agreement.

CHAPTER 45

Solitary waves passing over submerged breakwaters

Mark Cooker *
Howell Peregrine †

Abstract:

A method is described for the computation of the two-dimensional unsteady motion of a solitary wave passing over submerged breakwaters. Far from the breakwater the fluid is assumed static and the sea bed is level. The fluid motion is assumed to be irrotational, incompressible and inviscid. The exact boundary conditions at the free surface and the impermeable bed are satisfied. Laplace's equation for the velocity potential is solved using a boundary integral method.

Numerical results are reported which show the variety of ways in which solitary waves are distorted when they encounter submerged breakwaters.

This work is part of a program of study to provide more understanding of the hydrodynamics of steep waves when they encounter coastal structures. We have developed a computer program which models the motion of waves in 2D, irrotational, inviscid flows. The method is not restricted to any particular free surface motion but we choose here to examine solitary waves. This class of waves includes the largest 2D irrotational, inviscid wave which can steadily propagate on a fixed depth. Solitary waves are everywhere elevated above the undisturbed water level, so it was thought likely that these model the waves most damaging to structures. We can accurately reproduce solitary waves with heights up to 96% of the highest wave.

The numerical method employs a boundary integral technique to solve Laplace's equation for the velocity potential. Bernoulli's equation is used as one boundary condition at the free surface. We ignore surface tension, and take the atmospheric pressure above the liquid surface to be constant. The second boundary condition is to assume that fluid particles on the free surface stay on the surface. All rigid boundaries are assumed to be impermeable. Details of the method are given by Dold & Peregrine (1986).

The method is accurate, stable and efficient. A solitary wave of height 0.5 of the depth can propagate over a horizontal distance of 50 depths with less than 0.1% change in height. The method does not suffer from "sawtooth" instabilities.

The program can be run on an IBM-compatible AT personal computer: in 60 minutes elapsed time we can calculate the motion of a wave passing over a breakwater.

The method also uses conformal mappings to transform flow domains

*Research Assistant †Professor of Applied Maths
School of Maths, University of Bristol,
Bristol BS8 1TW, England.

with irregular beds into regions with a flat horizontal bed. This is done to make Laplace's equation easier to solve. For the examples used here the conformal mapping has a bottom comprising a semicircle (radius R) on an otherwise flat horizontal bed. See figure 1.

The solitary wave is started with its crest far enough from the semicircle for the wave to be unaffected by it in the first few time steps. The wave moves left towards the cylinder. The initial data describing an incident solitary wave is calculated using the method of Tanaka (1986).

Figure 1 : Solitary wave approaching submerged semicircular breakwater.

Let the undisturbed fluid depth $h = 1$. Then H , the incident wave height, and cylinder radius R , are dimensionless parameters. The $H - R$ parameter space is surprisingly rich: see figure 2. We expected all waves to steepen and break on the cylinder, but this only happens for the largest waves ($H > 0.6$) and the largest cylinders ($R > 0.8$) and even these extreme waves tend to break downstream of the breakwater.

Small cylinders ($R < 0.5$) cause very large, linearly unstable waves ($H > 0.8$) to eventually break, long after they have passed over the breakwater. See figure 3. Tanaka et al. (1987) show that unstable solitary waves do not necessarily break. The growth in time of the breakwater instability closely follows that discussed by Tanaka et al. (1987). Waves with height $H < 0.77$ develop a train of small dispersive waves in their wake, after they have passed over the breakwater when $R < 0.4$. See figure 4.

A very common but unexpected phenomenon occurs for many waves for cylinders with radius in the range 0.5 to 0.9. As the wave approaches the cylinder a second crest grows on the opposite side of the obstacle. The second crest grows and soon dominates the first which meanwhile decays. The new crest propagates away from the cylinder. This exchange of crests across the cylinder is reminiscent of a large solitary wave catching up a smaller one. See figure 5.

Most surprising of all are those waves of height between 0.3 and 0.6, passing over cylinders of radius 0.7 to 0.9. The wave passes over the breakwater and having cleared it a second, stationary wave forms above the left-hand margin of the breakwater. This second wave steepens enough to break over backwards, onto the cylinder. See figure 6.

For the example shown in figure 6 if we increase R from 0.7 to 0.8 the transmitted wave breaks forward before the second wave breaks backward. See figure 7. We are unable to continue the computations beyond the time at which a wave breaks, but experiments have indicated that breaking can occur for both of the waves. The breaking is simultaneous when $R=0.77$ for $H = 0.58$.

Wave tank experiments at Santander University in Spain by C ezar Vidal confirm the backwards breaker. Some measurements of depth as a function of time, at fixed stations, also agree well with prediction.

Figure 6 also illustrates the instantaneous streamlines of the flow. The pressure contours can also be found and the total force on the cylinder determined. For example when $H = 0.8$ and $R = 0.9$

the wave breaks on top of the cylinder. See figures 8 and 9. The horizontal and vertical components of hydrodynamic force on the breakwater as the wave approaches are plotted in figure 10. The maximum horizontal component of force occurs during the wave's approach and well before breaking. Both of the maxima in horizontal and vertical components of force are about as large as the hydrostatic force.

This shows how waves can exert large dynamical forces on submerged coastal structures.

Figures 11 and 12 show a sequence of profiles of a solitary wave of height 0.8 breaking on a shoal of elliptical profile. The bed is reminiscent of a gently shelving beach and our method has predicted the classical plunging breaker. The pressure distribution is plotted in figure 13, at a time soon after the front face of the wave has become vertical. The large pressure gradients normal to the front face of the wave and parallel to the bed remind us of the strength of the sea.

CHAPTER 46

LABORATORY EXPERIMENTS ON THE INFLUENCE OF WIND ON NEARSHORE WAVE BREAKING

Scott L. Douglass, A.M. ASCE ¹

J. Richard Weggel, F. ASCE ²

ABSTRACT

The influence of wind on nearshore breaking waves was investigated in a laboratory wave tank. Breaker location, geometry, and type depended upon the wind acting on the wave as it broke. Onshore winds tended to cause waves to break earlier, in deeper water, and to spill; offshore winds tended to cause waves to break later, in shallower water, and to plunge. A change in wind direction from offshore to onshore increased the surf zone width by up to 100%. Wind's effect was greatest for waves which were near the transition between breaker types in the absence of wind. For onshore winds, it was observed that micro-scale breaking can initiate spilling breaking by providing a perturbation on the crest of the underlying wave as it shoals.

INTRODUCTION

The most common breaker types on the open ocean coast are spilling and plunging. Spilling breakers are characterized by white-water at the crest which tumbles down the wave face until the entire wave face is a wall of tumbling white water. Plunging breakers are characterized by an unbroken wave face which steepens until it is vertical and then continues to curl over to form a surfer's "tube" before it plunges down on the base of the

wave face. Collapsing and surging waves, the other two breaker types, are more common on coastal structures and relatively steep beaches. These descriptive breaker types are subjective and the transition from one type to another is not always distinct.

It is well known that wave forces on structures can be extremely sensitive to breaker type. Plunging breakers can cause extremely high, short duration forces when a pocket of air is trapped between the wave face and the structure. It is also known that currents and sediment transport in the surf zone depend on breaker type and surf zone width. Breaker type has an effect on the wave height decay, energy decay, and turbulence across the surf zone, important factors in modeling surf zone dynamics.

Existing models of breaker type (Patrick & Wiegel, 1955; Galvin, 1968; Battjes, 1974) consider two independent dimensionless variables, the wave steepness and the beach slope. Battjes combines these variables in the surf similarity parameter and shows that nearshore breaker type and mechanics can be determined by ranges of the parameter.

There is little mention in the literature of the influence of wind on nearshore breaking waves. Three authors mention the effect in passing without agreement as to its importance. Walker (1974) states that offshore winds tend to cause breakers to plunge and that the optimum wind for surfing (surfers prefer plunging breakers) is a ten knot offshore wind. Walker reached this conclusion on the basis of his observations and a survey of recreational surfers. Kinsman (1965) mentions that an offshore wind is "conducive to the formation of plunging breakers," and that onshore winds contribute to producing spilling breakers. Kinsman goes on in jest that an offshore wind is a reason for graduate students at the University of Hawaii to cut class and go surfing. Peregrine (1983) states that wind effects on wave breaking are probably slight for moderate wind speeds. Neither Kinsman nor Peregrine discuss a basis for their statements.

Although the influence of wind on wave breaking has not been investigated and has rarely even been mentioned in the coastal engineering literature, it is well known by fishermen, surfers, lifeguards and others who spend much time in the surf. The first author has often observed an influence of wind on wave breaking along the southern New Jersey shore. The wind shift from a light land breeze to a sea breeze which occurs many summer days changes the breakers from plungers to spillers. A thunderstorm which quickly changes the wind direction from a sea breeze to a land breeze can dramatically change the breaker type from spilling to plunging within seconds.

This investigation was conducted to fill a gap in the knowledge about the effect of local wind on the nearshore, depth-limited breaking of individual waves. The primary objective was to qualitatively and quantitatively determine what effects winds have on breaking and to investigate the physical explanation of the phenomenon.

EXPERIMENTAL FACILITIES

Experiments on the influence of wind on shoaling breakers were conducted in the glass wave tank at Drexel University. The tank is 35 m long, 0.76 m deep and 0.91 m wide. The tank has glass walls and a glass bottom with aluminum supports spaced every 1.52 m along its length. At one end of the tank is a piston-type wave generator capable of generating monochromatic waves.

A plywood beach and splitter wall were installed beginning 17 m from the wave generator. The splitter wall was located midway across the breadth of the tank and divided the tank into two sections (see Figure 1). On one side of the splitter wall, a rigid 1:25 sloping plywood beach was constructed. On the other side of the splitter wall were the two-by-four bracing for the beach and a wave-absorbing pile of rubble at the far end from the wavemaker. All the seams between the splitter wall and beach and beach and glass walls were sealed.

A plywood cover roof was constructed over the beach section of the flume and a variable-speed, bi-directional fan was installed on the upper end of the beach above the level of wave runup. All the seams in the roof section were sealed with duct tape. This arrangement allowed wind to be blown offshore or drawn onshore over the beach section. A honeycomb was placed in the airflow one meter from the fan. A bell-shaped mouth piece was constructed at the open end of the covered beach section to allow smooth entry of the onshore wind.

EXPERIMENTAL PROCEDURES

Video recording was the primary method of measuring the location of the water surface in the shoaling and breaking waves. A thin, black 2 cm x 2 cm grid on clear plexiglass sheets was attached to the front glass sidewall. During video recording, the room was darkened and the water was lit from below the waterline with lights clipped on the outside of the glass sidewall. This

Figure 1. Wave tank schematic

avoided glare and reflection problems from the plexiglass and glass and allowed the water surface to be easily seen through the grid and against the white splitter wall. The recording was done with two goals in mind:

- 1) to measure the variation in water surface elevation in space at an instant in time (i.e. a snapshot of the water surface elevation),
- 2) to measure the variation of water surface elevation in time at a specific location along the beach (i.e. a wave gage).

The video tapes were viewed on a professional video editing system with stop-action, frame-by-frame advance, frame counting capability, and a high resolution video screen. Water surface elevation vs. time and elevation vs. distance information were manually viewed during data reduction.

Windspeeds were measured using a pitot tube and micro-manometer. The pitot tube was extended through the plywood cover roof down into the air duct above the beach section.

WAVE AND WIND CONDITIONS TESTED

The range of experimental conditions were selected to produce spilling breaker conditions and plunging breaker conditions when there was no wind. Three different wave conditions; designated S, I, and P; were selected. Wave "S" broke in a spilling manner in the absence of wind. Wave "I" (for Intermediate) was chosen to be as close to the limit between the two breaker types as possible. It was chosen by holding the piston stroke length constant and varying the motor speed until the breaker type switched. The stop action of the video showed that the breaker type varied across the wave tank. The front one-third of the wave (the third adjacent to the glass sidewall) was spilling but along the rest of the wave crest a small jet was visible. A slightly steeper wave spilled evenly across the entire beach and a slightly less steep wave plunged evenly across the entire beach. This cross-tank variation in breaker type was used as an indicator of the midpoint of the demarcation between breaker types. Wave "P" was of very low steepness and clearly plunged.

Wind direction was defined as follows: wind in the direction of wave propagation, i.e. a sea breeze, was called onshore wind; wind in the opposite direction of wave propagation, i.e. a land breeze, was called offshore

wind. The sign convention adopted was onshore winds positive and offshore winds negative.

Thirteen different sets of tests were run using the three wave conditions and the five wind conditions. The test conditions are summarized in Table 1. The low windspeeds were approximately of the same magnitude as the wave celerities. The high windspeeds were approximately twice the wave celerities. Wave steepnesses (H/L) and wave celerities are as calculated in the flat portion of the tank.

RESULTS

Breaker Type

Table 2 shows the changes in breaker type due to wind (S-spilling, P-plunging). Wind changed the breaker type for both waves "I" and "S". In the absence of wind, wave "I" was intermediate between spilling and plunging. With an onshore wind the breaker distinctly spilled. With an offshore wind the breaker distinctly plunged. Wave "S", which spilled in the absence of wind, plunged with an offshore wind. Wind did not effect the breaker type for wave "P" which was always plunging. Wind had little effect whatsoever on wave "P".

Breaker Location and Width of Surf Zone

The change in breaker location was one of the most visually obvious effects of wind on wave breaking. Breaking was defined as the moment the front face became vertical or started to entrain air. The change in surf zone width (defined as the horizontal distance from the breaker location to the intersection of the still water level and the beach) as a function of the ratio of wind velocity, U , to wave celerity, C , is shown in Figure 2. Acceleration due to gravity, g , and wave period, T , are used to non-dimensionalize the breaker depth, d . For wave "I", the surf zone width was 43% narrower with the high offshore wind than with no wind. The change in wind direction from high offshore to high onshore about doubled the surf zone width. For wave "S", the changes were not as large but were still significant. For wave "P", the change in breaker location was much smaller.

Breaker Height to Depth Ratio

The influence of wind on the breaker height to depth ratio is shown in Figure 3. Most of the influence of wind on breaker height to depth ratio is due to wind's effect on breaker depth (Figure 4). The effect of wind on

Figure 2. Effect of wind on surf zone width.

Figure 3. Effect of wind on breaker height to depth ratio.

Figure 4. Effect of wind on breaker depth.

Figure 5. Effect of wind on breaker height.

breaker height (Figure 5) is only 5 to 10%. Height was defined as crest to trough height at the point of breaking. Depth was defined as the vertical distance from the still water level to the bottom. Set-down and wind's effect on set-down were found to be smaller than the experimental error introduced by the resolution of the video procedure.

The above results show that wind's influence on breaking was greatest for waves which were near the transition between breaker types in the absence of wind, waves "1" and "S". Wave "P" had such a low steepness it was closer to the transition to collapsing/surging than to the transition to spilling. It was barely effected by the wind.

DISCUSSION

The recent numerical studies of breaking waves using potential flow theories (see New, et al., 1985) supplemented by observations (Basco, 1985) have led to the concept that both plunging and spilling breaking are due to the same hydrodynamic instability. The difference between spilling and plunging waves is the size of the jet. This study does not contradict this concept but shows that the approach to such breaking may be physically unstable to perturbations such as wind shear.

The video recordings of the onshore wind tests for waves "S" and "1" showed that the spilling breakers were initiated by a micro-scale breaking wave. Micro-scale breaking waves occur on the crests of the underlying longer waves due to the shearing effect of the wind (Phillips, 1977). Most of these micro-scale breakers are short-lived but as the primary underlying wave shoals, eventually one of the micro-scale breakers is the instability which triggers spilling of the primary wave. Thus, it appears that the wind effect is enough to trigger the initiation of breaking for waves which are approaching but not yet at the point of breaking in the absence of wind. Spilling breaking occurred farther offshore as the onshore wind speed was increased.

The mechanisms responsible for the influence of an offshore wind on breaking waves appear to be a reduction in shoaling combined with surface wind drag and perhaps wind pressure differences. Wind drag prevents small instabilities from tumbling forward down the wave face. Once a jet begins to form, the shear layer is probably of little importance since it is thin compared with the thickness of the jet. By that point, the water surface is vertical on the front face and the distribution of

pressure due to the wind can play a more significant role. It was found that the offshore wind effectively retarded the last stages of wave shoaling. This explains the waves propagating farther inshore before breaking. The reduced wave height at a specific location on the beach may be due to interactions between the offshore-propagating, wind-driven ripples and the primary wave. The reduced wave height implies a lower steepness which would tend toward a plunging breaker for a fixed beach slope.

SUMMARY

Laboratory studies show that breaker location, type, and geometry depend critically upon the wind acting on the wave as it breaks. Onshore winds tend to cause waves to break earlier, in deeper water, and to spill. Offshore winds tend to cause waves to break later, in shallower water and to plunge.

CHAPTER 47

WAVE RUN-UP PREDICTION VS. MODEL TEST RESULTS: A COMPARISON

PETER E. GADD¹
VICTOR MANIKIAN²
JERRY L. MACHEMEHL³

ABSTRACT

Large-scale physical model test measurements of wave run-up are compared with wave run-up prediction derived from the Shore Protection Manual (SPM). Noteworthy discrepancies between the results of these two methods have been identified that include substantial overestimation of wave run-up elevations using the SPM approach, and computation of roughness coefficient values that vary as a function of wave steepness. The slope armors tested in the study at model scales of 1:3 and 1:4 include linked concrete matting and overlapped gravel-filled fabric bags.

INTRODUCTION

Accurate prediction of wave run-up elevation is an important element in the design of coastal and offshore structures. Should the design process result in a run-up elevation prediction that is too low, serious flooding of the structure work surface may result. Conversely, if the predicted wave run-up is too high, the cost of the structure will be unnecessarily expensive due to the implementation of fill quantities and slope armor that are not truly required. The methods available to predict wave run-up on a particular structure include empirical techniques, such as those set forth in the Shore Protection Manual (U.S. Army Corps of Engineers, 1984), and the performance of a physical model to simulate wave run-up for the structure and oceanographic conditions under study.

1. Principal, Coastal Frontiers Corporation, Altadena, California, U.S.A.
 2. Staff Civil Engineer, Arco Alaska, Inc., Anchorage, Alaska, U.S.A.
 3. Professor, Texas A & M University, College Station, Texas, U.S.A.

In recent years, we have collected large-scale physical model data of breaking wave run-up. This data can be used to determine the accuracy with which empirical prediction techniques match results from the large-scale modelling efforts.

The objective of this presentation is two-fold:

1) To provide a direct comparison of large-scale physical model study results of wave run-up to estimated values generated from conventional wave run-up prediction techniques as presented in the Shore Protection Manual.

2) To provide large-scale wave run-up values for two relatively obscure shore protection armors--large overlapped gravel-filled bags and linked concrete block matting. These armor types have proven to be useful in providing protection against moderate wave impact at project sites where more substantial materials (quarystone, large concrete units) are unavailable and/or uneconomical.

LARGE-SCALE WAVE RUN-UP DATA

Figure 1 provides a definition sketch for the wave run-up process. A wave exhibiting an unrefracted deepwater wave height and wavelength (H_0' and L_0) and period (T), impacts a slope having an inclination angle (θ) in a still water depth (d_s). The height of wave run-up (R) on the slope of the structure is measured as a vertical elevation above the still water line (SWL).

FIGURE 1: WAVE RUN-UP DEFINITION SKETCH

The model tests summarized herein were performed at the Oregon State Wave Research Facility, Corvallis, Oregon, U.S.A., in February-March, 1984. The wave tank is 104 m (340 ft) in length, 3.7 m (12 ft) wide, and the water depth was varied to accurately simulate the 2.5 - 5.2 m (8 - 17 ft) water depth range that was expected to exist at the prototype location. The size of the wave

tank allowed the model tests to be conducted at scales of 1:3 and 1:4. Wave heights under study ranged from prototype values of 1.5 - 3.0 m (5 - 10 ft). While both monochromatic and irregular wave trains were studied during the course of the model test program, only the results of the monochromatic breaking wave tests are reported herein. The range of values of the Surf Similarity Parameter ($= \tan\theta (H/L_0)^{-1/2}$) exhibited by the waves in this study was 1.1 - 3.5, corresponding primarily to plunging and collapsing breakers.

Wave height in the model test was measured using an acoustic water level profiler secured above the wave tank. A graduated tape was firmly affixed to the slope allowing the investigator to carefully observe the position of the still water level prior to testing, and the elevation of wave run-up. Conventional surveying of the slope allowed a correlation to be developed between each value noted from the graduated tape and the corresponding elevation relative to the still water level.

Slope armors that were tested in the model study included linked concrete matting of two different types, and large gravel-filled fabric bags (prototype bag weight = 6,000 kg (13,200 pounds)). These armor types have been extensively used in the Alaskan Arctic offshore, the site of the structure under consideration (Gadd, 1988; Leidersdorf, 1988). In addition, gravel bags and concrete matting have been studied and utilized in moderate wave climates in more temperate areas of the world (Breteler, *et al.*, 1988; Heerten, *et al.*, 1988; for example), where more durable armor types are unavailable, too costly, or inappropriate due to the temporary nature of the slope protection required.

The concrete mat exhibits a very smooth slope surface, interrupted only by the regular voids at the spaces between adjacent blocks. The gravel bag slopes exhibit a substantial bag overlap of 50% of the bag length. The resulting slope is "stair-stepped", a cross-section that is effective in dissipating wave run-up. Both armors studied were placed on permeable filter fabric overlying a smooth gravel slope inclined at an angle of 1V:3H (18.4° from horizontal).

CONVENTIONAL WAVE RUN-UP PREDICTION

In the absence of physical model study data collected for a particular structure and ocean environment, the coastal engineer must rely on predictive techniques developed for more generalized structures and oceanographic conditions. While numerous methods exist world-wide for this engineering task, perhaps the most popular means in the United States is the use of the wave run-up diagrams presented in the Shore Protection Manual (SPM). The basis for the methods presented in the

SPM are the numerous model tests of wave run-up undertaken by the U.S. Beach Erosion Board in the 1950's. These studies dealt only with the idealized conditions of monochromatic waves impacting structures in which the slopes were planar, smooth, and impermeable. The majority of these model tests can be considered to have been performed at "small scale" (typically, model scales of 1:17 or 1:30 were employed) (Saville, 1987).

Wave run-up prediction taken from the SPM curves requires computation of the wave steepness parameter, H_o'/gT^2 . The value of the wave run-up elevation, R , for a particular structure slope angle and wave steepness parameter is given in the SPM for relative depth values, d_s/H_o' , of 0.0, 0.45, 0.8, 2.0, and ≥ 3.0 . The family of curves given for a relative depth ≥ 3.0 is shown in Figure 2. As dictated by the SPM, wave run-up values taken from these curves require modification to account for scale effect and slope roughness and permeability prior to establishing the predicted run-up value.

FIGURE 2: EXAMPLE OF SPM RUN-UP CURVES

The scale effect correction prescribed for use in the SPM is presented in Figure 3. This relationship that indicates an increasing scale effect with increasing structure slope was developed using limited test data collected at three values of structure slope: 1:3, 1:6, and 1:15. A description of the large-scale testing and the rationale supporting the selection of this scale effect correction has been recently presented by Saville (1987).

FIGURE 3: SPM RUN-UP CORRECTION FOR SCALE EFFECTS

The wave run-up reduction from the SPM curves necessitated by slope roughness and permeability is expressed by the "roughness coefficient", r . Based on research by Battjes (1974), the SPM specifies an individual value of " r " for a variety of armor types, as indicated in Table 1. As is evident, the maximum value of run-up coefficient for a permeable slope is 0.9, given for concrete blocks. For highly permeable quarystone slope armor, the SPM suggests that the roughness coefficient can be as low as 0.45. While no value is given in the SPM for gravel bag armor, we presume that the value given for rounded quarystone ($r = 0.60 - 0.65$) is most appropriate for use in the comparison presented herein.

TABLE 1: ROUGHNESS COEFFICIENTS FOR VARIOUS ARMORS

Slope Surface Characteristics	Placement	r
Smooth, impermeable	-----	1.00
Concrete blocks	Fitted	0.90
Basalt blocks	Fitted	0.85 to 0.90
Gobi blocks	Fitted	0.85 to 0.90
Grass	-----	0.85 to 0.90
One layer of quarystone (impermeable foundation)	Random	0.80
Quarystone	Fitted	0.75 to 0.80
Rounded quarystone	Random	0.60 to 0.65
Three layers of quarystone (impermeable foundation)	Random	0.60 to 0.65
Quarystone	Random	0.50 to 0.55
Concrete armor units (~ 50 percent void ratio)	Random	0.45 to 0.50

COMPARISON OF RESULTS

A number of figures have been prepared to illustrate the comparison between the predicted run-up values as determined by the SPM techniques and the actual data measured in the physical model study performed at scales of 1:3 and 1:4. As is the case in the SPM, the relative run-up (R/H_o') is plotted against the wave steepness parameter, H_o'/gT^2 . All of the data collected represents the single side slope value of 1V:3H (18.4° from horizontal).

Concrete Mat Armor

Figure 4 shows the wave run-up diagram for linked concrete mat armor and a relative depth, d_s/H_o' , greater than or equal to 3.0. The solid curve indicates the smooth slope SPM prediction with the scale effect correction applied. A constant roughness coefficient, $r = 0.9$, is applied to the smooth slope curve to yield the dotted curve which represents the SPM run-up prediction for concrete mat armor. As is evident, the measured data lies below the predicted curve. As the wave steepness parameter, H_o'/gT^2 , decreases, the discrepancy increases between the SPM prediction and the measured data. Indeed, for small values of wave steepness parameter, the SPM technique overpredicts the wave run-up elevation by nearly 100% relative to the model test data.

FIGURE 4:
WAVE RUN-UP
CONCRETE MAT

A determination of the measured roughness coefficient, r , for each data point has been plotted as a function of wave steepness parameter in Figure 5. While the SPM methods suggest a constant "r" value of 0.9 for

the concrete mat, the data indicates that the value of "r" varies from 0.4 to 0.8 over the range of wave steepness that was tested. While scatter does exist in the data, it seems clear that the SPM overpredicts wave run-up relative to the data measured, and the roughness coefficient, "r", increases with increasing wave steepness.

FIGURE 5:
CONCRETE MAT
ROUGHNESS COEFFICIENT, "r"

Figures 6 and 7 are presented to show wave run-up and roughness coefficient characteristics for the concrete mat armor for relative depths, d_s/H_o' , of approximately 2.0. While both the predicted wave run-up and the measured data are marginally larger for this case, a similar trend is indicated as that noted previously for the value of relative depth, d_s/H_o' , ≥ 3.0 . In this case, the value of the roughness coefficient, r, suggested by the SPM ($r = 0.9$) fits the data for values of the wave steepness parameter, H_o'/gT^2 , that exceed 0.011. Below this value, however, "r" decreases to as low as about 0.4.

Overlapped Gravel Bags

For gravel bag armor, similar trends exist as those noted previously for concrete mat armor. To predict wave run-up using the SPM approach, we have selected a roughness coefficient value of 0.60 from the SPM to typify the gravel bag slope. Due to the irregular nature of the gravel bag armor, a greater degree of data scatter is indicated than that seen previously for the concrete

mat. In Figure 8, for the relative depth value, $d_s/H_o' \geq 3.0$, most of the data falls below the SPM prediction, although the trend of the data appears to suggest that the SPM methods represent an upper bound for the model test results. Figure 9 indicates that the roughness coefficient value for this case appears to be less dependent on wave steepness with a constant value of 0.45 being applicable. Should a greater degree of conservatism be desired, a value of "r" of 0.60 is a reasonable choice.

As shown in Figure 10, in which the relative depth value is approximately 2.0, the gravel bag slope again indicates overprediction of wave run-up using the SPM methods, however, the functional dependence on wave steepness is not clearly defined. A constant value of "r" of 0.50 seems to be applicable to gravel bag slopes for this relative depth value, as shown in Figure 11.

CONCLUSIONS

For two specific slope armor types, overlapped gravel bags and linked concrete matting, comparison of measured data from large-scale physical model studies with wave run-up prediction methods presented in the SPM suggests the following:

- 1) The SPM predictive methods overpredict wave run-up. Particularly in the case of concrete mat slope protection, the degree of discrepancy between the results of the SPM methods and the measured data appears to be dependent on the wave steepness. For small values of the wave steepness parameter, H_o'/gT^2 , the measured data is on the order of one-half of the predicted value.

- 2) For concrete mat armor, a variable roughness coefficient, "r", is indicated. The value of "r" varies from about 0.4 for $H_o'/gT^2 = 0.002$, to 0.9 for $H_o'/gT^2 = 0.13$.
- 3) Because no value of roughness coefficient for overlapped gravel bags is given in the SPM, it is not possible to precisely judge the predictive accuracy of the SPM for this armor type. Use of an "r" value of 0.6 (suggested by the SPM for rounded quarystone) slightly overpredicts wave run-up for gravel bag armor. The discrepancy between the predicted and measured run-up values is not as great as that noted for concrete mat armor. Unlike the results of the concrete mat research, the roughness coefficient for gravel bags does not appear to be strongly dependent on wave steepness. Selection of a constant roughness coefficient of 0.5 - 0.6 for overlapped gravel bag armor seems appropriate over the range of our experimental data.

CHAPTER 48

STATISTICAL PROPERTIES OF THE MAXIMUM RUN OF IRREGULAR SEA WAVES

by Akira Kimura

ABSTRACT

The probability distribution of the maximum run of irregular wave height is introduced theoretically. Probability distributions for the 2nd maximum, 3rd maximum and further maximum runs are also introduced. Their statistical properties, including the means and their confidence regions, are applied to the verification of experiments with irregular waves in the realization of a "severe sea state" in the test.

1. INTRODUCTION

The importance of bringing the statistical nature of irregular sea waves into the design concepts of coastal structures has been widely recognized. Hydraulic tests with irregular waves in a wave tank have become one of the standard techniques to investigate dynamic properties of coastal and ocean structures. Simulation and generation techniques of irregular sea waves have been developed and applied for this purpose.

The group nature of irregular sea waves, on the other hand, has been clarified recently. Since there is a correlation between consecutive wave heights (and period), high waves (or low waves) tend to arrive in groups. This means that high waves tend to arrive intermittently in groups and that there are long durations between them, in which low waves consecutively arrive. Irregular wave simulation techniques are mainly directed to simulate the averaged properties of irregular sea waves, i.e. wave spectrum, probability distribution for wave height and period, etc. A long term steady state for these properties is designed to be simulated in the techniques except for the simulation of definite wave profiles. However, those properties measured in a short duration are not always guaranteed to be the same as the designed ones but rather distribute around them statistically. Therefore, hydraulic tests which are carried out in durations in which no high wave run arrives may bring about an under-estimation of wave effects. Insufficient estimation from the test, especially under-estimation, may induce deficiencies in the design for prototype structures. Model tests always have a possibility of missing the temporal "severe sea state" if the test is not sufficiently long. However, there have, in fact, been no established criterion used in

Associate Prof. Tottori Univ., Koyama Minami 4-101, Tottori, Japan

the verification of test results regarding whether the severe sea state is realized during the test. In addition to ordinary criteria, then, a new criterion which can be a measure for the temporal state of irregular sea waves becomes necessary and the property of the high wave group, especially its maximum value, may be suitable for this. This study aims at clarifying the statistical properties of the maximum run of high waves which may be a good measure for the temporal "severe sea state". The statistical properties of the 2nd maximum, 3rd maximum, and further maximum runs of high waves are also clarified and confidence regions for their means are given and explained in the examination of the effectiveness of the model test in this study.

2. PROBABILITY DISTRIBUTION OF THE MAXIMUM RUN OF HIGH WAVES

The author has introduced the probability distribution of the maximum run of high waves to apply for "short term overtopping" (Kimura, 1984). It can be summarized as follows:

Assuming the time series of wave height to be the Markov chain, the probability distribution of a run of waves which exceed the threshold wave height (h_t) consecutively is given as (Kimura, 1980)

$$P_1(\ell) = p^{\ell-1}(1-p) \quad (1)$$

in which p is given by

$$p = \frac{\int_{h_t}^{\infty} \int_{h_t}^{\infty} P_0(h_1, h_2) dh_1 dh_2}{\int_{h_t}^{\infty} Q_0(h_1) dh_1} \quad (2)$$

P_0 is the two dimensional Rayleigh distribution while Q_0 is the Rayleigh distribution. These are given as follows (wave height is normalized by the mean wave height throughout this study):

$$P_0(h_1, h_2) = h_1 h_2 / A \cdot I_0(h_1 h_2 \rho / A) \exp\{-(h_1^2 + h_2^2) / \pi A\} \quad (3)$$

$$Q_0(h_1) = \pi h_1 / 2 \exp(-\pi h_1^2 / 4) \quad (4)$$

$$A = 4 / \pi^2 - \rho^2 \quad (5)$$

in which I_0 is the modified Bessel function of the 1st kind, and ρ is a correlation parameter between consecutive wave heights. This has the following relation with a correlation coefficient of consecutive wave heights.

$$\gamma_h = \{E(\pi \rho / 2) - (1/2)(1 - \pi^2 \rho^2 / 4)K(\pi \rho / 2) - \pi / 4\} / (1 - \pi / 4) \quad (6)$$

K and E are the complete elliptic integrals of the 1st and 2nd kinds, respectively.

The probability distribution of the maximum run in a population of high wave runs of size N is introduced as follows:

The probability that the run is equal to or smaller than $\ell - 1$ is given

as

$$P_2(\ell) = \sum_{\ell'=1}^{\ell-1} p^{\ell'-1} (1-p) = (1-p)^{\ell-1} \quad (7)$$

Therefore, all runs in the population are equal to or smaller than $\ell - 1$ giving $(1-p)^{\ell-1} N$, assuming all runs to be independent. On the other hand, the probability that at least one or more runs in the population are equal to or greater than ℓ is given as $1 - (1-p)^{\ell-1} N$. In the same way, the probability that at least one or more runs are equal to or greater than $\ell + 1$ is given as $1 - (1-p)^{\ell} N$. The probability that the maximum run becomes ℓ is, therefore, given as

$$P_3(\ell) = (1-p)^{\ell} N - (1-p)^{\ell-1} N = \exp\{N \cdot \ln(1-p)^{\ell}\} - \exp\{N \cdot \ln(1-p)^{\ell-1}\} \quad (8)$$

in which \ln is the natural logarithm.

Equation (8) is shown in Fig.1; (a) $N=100$ and (b) $N=1,000$. The 1/10 maximum wave (solid line), the significant wave (chain line) and the mean wave (broken line) heights are used for h_t respectively.

(a) $N=100$

(b) $N=1000$

Fig.1 Probability distribution of the maximum run of high waves

Example 1 (duration and number of runs)

Giving a duration and wave properties, the probability distribution of the maximum run of high wave is given as follows:

An expected number of high wave runs N within a duration D is given by

$$N = D / \ell_t T_m \quad (9)$$

in which ℓ_t is a mean of the total run (recurrence interval of the runs) of high waves and T_m is a mean wave period. We assume here a steady sea state, its spectrum to be the Pierson-Moskowitz type (for simplicity this spectrum is used throughout this study; the spectrum gives affect on the correlation parameter ρ in eq.3, Battjes and van Vledder,1984), $h_t=1.6$ (significant wave height) and $T_m=10s$. The averaged value of the total run is given by (Kimura,1980),

$$\ell_t = 1/(1-p') + 1/(1-p) \quad (10)$$

in which p is given by eq.(2) and p' is given by

$$p' = \frac{\int_0^{h_t} \int_0^{h_t} P_0(h_1, h_2) dh_1 dh_2}{\int_0^{h_t} Q_0(h_1) dh_1} \quad (11)$$

Substituting $\rho=0.247$ (Pierson-Moskowitz spectrum; Kimura,1980) and $h_t=1.6$, we obtain $\ell_t=10.2$. The expected number of high wave runs is calculated as

$$N = D / 10.2 \times 10 \quad (12)$$

If we use 1 week for the duration ($D=604800s$) we obtain $N=5929$. Substituting values of p and N into eq.(8), we obtain the probability distribution of the maximum run of wave height ($h >$ significant wave height) which appears once a week. The relations between h_t and ℓ_t for the representative wave heights are listed in Table-1.

Table-1 h_t and ℓ_t

h_t	ℓ_t
1.0 (H_{mean})	4.7
1.60 ($H_{1/3}$)	10.2
2.03 ($H_{1/10}$)	30.1

3. MEAN OF THE MAXIMUM RUN OF HIGH WAVES

From eq.(8), the mean of the maximum run is introduced as

$$\sum_{i=1}^N N^C_i \frac{(-1)^{i+1}}{1-p^i} \quad (13)$$

Since this equation is difficult to carry out in practice when N and i are large, the following approximation is applied (Longuet-Higgins,

1952).

Applying ℓ_0 , which is given by the equation $N \cdot p^{\ell_0} = 1$, $(1-p^\ell)^N$ in eq.(8) is written as

$$(1-p^\ell)^N = (1-p^{\ell - \ell_0} / N)^N$$

Since $p < 1$, for large values of N the above equation reduces to

$$(1-p^{\ell - \ell_0} / N)^N \approx \exp(-p^{\ell'}) \tag{14}$$

in which $\ell' = \ell - \ell_0$

and $\ell_0 = -\ln(N) / \ln(p)$ (15)

The general form of eq.(14) is shown in Fig.2 (solid line). If N is sufficiently large, eq.(14) asymptotically approaches to

$$\exp(-p^{\ell'}) \approx \begin{cases} 0 & \ell' < \ell_*' \\ 1 & \ell' > \ell_*' \end{cases} \tag{16}$$

in which ℓ_*' is a point which makes equal the upper and lower shadowed portions between eq.(14) and eq.(16) (Fig.2),

$$\begin{aligned} \ell_*' &= \int_0^\infty 1 - \exp(-p^{\ell'}) d\ell' - \int_{-\infty}^0 \exp(-p^{\ell'}) d\ell' \\ &= -\gamma / \ln(p) \end{aligned} \tag{17}$$

in which γ is Euler's constant ($= 0.5772\dots$). In the same way, $(1-p^{\ell-1})^N$ in eq.(8) is given approximately as

$$(1-p^{\ell-1} / N)^N \approx \exp(-p^{\ell'-1}) \approx \begin{cases} 0 & \ell' < \ell_*'+1 \\ 1 & \ell' > \ell_*'+1 \end{cases} \tag{18}$$

From the definition, the mean of the maximum run is given as

$$\ell_{1*} = \sum_{\ell=1}^\infty \ell P_3(\ell) \tag{19}$$

From eqs.(16) and (18),

$$\ell_{1*} = \sum_{\ell = \ell_0 + \ell_*'}^{\ell_0 + \ell_*' + 1} \ell \tag{20}$$

Since $\ell_0 + \ell_*'$ is not an integer in general, ℓ_{1*} is the integer between $\ell_0 + \ell_*'$ and $\ell_0 + \ell_*' + 1$. Extending the definition for ℓ into real numbers and approximating the probability of ℓ between $\ell_0 + \ell_*'$ and $\ell_0 + \ell_*' + 1$ with eqs.(16) and (18), we obtain an expected mean of the maximum run as

$$\ell_{1*} = \ell_0 + \ell_*' + 1/2 = -(\ln(N) + \gamma) / \ln(p) + 1/2 \tag{21}$$

Fig.2 Approximation of eq.(14)

If we apply eq.(1) for the probability of ℓ in the same interval instead, we obtain,

$$\ell_{1*} = \ell_0 + \ell_*' + \int_{\ell_0 + \ell_*'}^{\ell_0 + \ell_*' + 1} \ell p^{\ell-1} (1-p) d\ell / \int_{\ell_0 + \ell_*'}^{\ell_0 + \ell_*' + 1} p^{\ell-1} (1-p) d\ell$$

$$= -(\ln(N) + \gamma) / \ln(p) - 1/\ln(p) + p/(p-1) \tag{22}$$

Figure 3 shows the relation between ℓ_{1*} and N. The approximation of eq.(22) is used in the calculation.

Example 2 (mean of the maximum run)

If we use the same conditions applied in Example 1 ($h_t=1.6$; significant wave height, $T_m=10s$), the expected mean of the maximum runs during 1 day, 1 week and 1 month are calculated as follows.

Table-2 D,N and ℓ_{1*}

duration	number of waves	number of runs	maximum run (eq.22)
1 day	8640	847	6.0
1 week	60480	5929	7.5
1 month	259200	25412	8.6

The number of runs is given by dividing the number of waves by the mean of the total run (10.2; $h_t=1.6$).

Fig.3 Expected mean of the maximum run

4. VERIFICATION OF THE EXPERIMENTAL RESULT

As explained in the introduction, high waves tend to arrive in groups. Therefore, if a short duration for the model test is applied, the possibility of missing high wave runs during the test may be large. Since a high wave or its group may actually have the greatest effect on coastal structures, the reliability of the model test is highly affected by the frequency of high waves and high wave runs which appear during the test. If a long duration is applied for the test, the statistical properties of the high wave run can be investigated by the ordinary theory (Kimura, 1980). However, if a short duration is applied, the verification of the test is difficult due to an insufficient number of runs. When tests with 100 irregular waves are carried out, for example, we can investigate the ordinary properties such as the power spectrum, wave height distribution, etc. However, it may be difficult to investigate the results regarding the severity of the sea state for the model, since only 10 (roughly) high wave runs are expected if we apply the significant wave height for h_t . In this section, for verification of the efficiency of the model test which is short in duration, the ordered statistics of the run of high waves are investigated.

In the population of N independent high wave runs of $h > h_t$, the probability that i runs are equal to or greater than ℓ and that the other $N-i$ runs are equal to or smaller than $\ell-1$ is given as

$$P_G(\ell)^i \cdot P_L(\ell)^{N-i} \quad (23)$$

in which P_G and P_L are the probabilities that a run is greater than or equal to ℓ and equal to or smaller than $\ell-1$ respectively,

$$\begin{aligned} P_G(\ell) &= \sum_{\ell'=1}^{\infty} p^{\ell'-1} (1-p)^{p^{\ell-1}} \\ P_L(\ell) &= \sum_{\ell'=1}^{\ell-1} p^{\ell'-1} (1-p)^{(1-p)^{\ell-1}} \end{aligned} \quad (24)$$

There are $N C_i$ combinations to select i runs among N runs. Therefore, the probability that all i runs selected are equal to or greater than ℓ and that the remaining $N-i$ runs are equal to or smaller than $\ell-1$ is given as

$$N C_i \cdot P_G(\ell)^i \cdot P_L(\ell)^{N-i} \quad (25)$$

The probability that at least $n+1$ ($n=1,2,$) runs are equal to or greater than ℓ is given as

$$1 - \sum_{i=0}^n N C_i \cdot P_G(\ell)^i \cdot P_L(\ell)^{N-i} \quad (26)$$

In the same way, the probability that at least $n+1$ runs are equal to or greater than $\ell+1$ is given as

$$1 - \sum_{i=0}^n N C_i \cdot P_G(\ell+1)^i \cdot P_L(\ell+1)^{N-i} \quad (27)$$

Consequently, the probability that the $(n+1)$ -th maximum run ($n=1,2, \dots$) equals to ℓ is given as

$$P_{n+1}(\ell) = \sum_{i=0}^n N C_i \{ p^i \ell (1-p)^\ell \}^{N-i} p^{i(\ell-1)} (1-p)^{\ell-1} \}^{N-i} \quad (28)$$

The distribution function of P_{n+1} is given as

$$F_{n+1}(\ell) = \sum_{i=0}^n N C_i \cdot p^i \ell (1-p)^\ell \}^{N-i} \quad (29)$$

(The above equations also hold for $n=0$; maximum run.)

Applying the same approximation as in eqs.(16) and (18), the mean of the $(n+1)$ -th maximum run ($n=1,2, \dots$) is given as

$$\ell_{(n+1)*} = \ell_{1*} - \sum_{i=1}^n N C_i \left\{ \sum_{\ell=\ell_{1*}}^{\infty} \left(\frac{p^\ell}{1-p^\ell} \right)^i \right\} \quad (30)$$

($n \geq 1$)

in which ℓ_{1*} is given by eq.(21) or (22). The definition for ℓ is extended into real numbers again in this equation. The summation with respect to ℓ is taken for the values at $\ell = \ell_{1*}, \ell_{1*+1}, \ell_{1*+2}$, and so on.

If measured values of $\ell_{(n+1)*}$ ($n=1,2,3, \dots$) fall within a significant part of the distribution (eq.28), the experimental data may be judged to be statistically significant. When we apply the 95%* or the 99%* confidence intervals, we may consider the data to be statistically significant if $\ell_{(n+1)*}$ falls within the intervals between $\ell_{(n+1)*-} - \ell_c$ and $\ell_{(n+1)*+} + \ell_c$. ℓ_c is a half of the confidence interval for the given confidence coefficient and is given by solving eq.(29) implicitly .

* (traditional standards are adopted, i.e. 95% and 99%.)

$$\left| \sum_{i=0}^n N C_i p^i \ell (1-p)^\ell \}^{N-i} \right| \begin{matrix} \ell_{(n+1)*+} + \ell_c \\ \ell_{(n+1)*-} - \ell_c \end{matrix} = 0.95 \text{ or } 0.99 \quad (31)$$

($n=0,1,2, \dots$)

To have an exact value for ℓ_c in the above equation, the definition for ℓ has to be extended into the real numbers.

Figures 4 (a) and (b) show the changes in the confidence regions of the maximum run with respect to N when (a) the significant wave height and (b) the 1/10 maximum wave height are used for h_t respectively. The dotted line is for the 95% and the chain line is for the 99% confidence regions respectively. Figures 5 (a) and (b) show the changes in the confidence regions of the maximum run with respect to h_t when (a) $N=50$ and (b) $N=500$ are used respectively.

Example 3 (statistically significant run)

When $N=100$ and $h_t=1.6$, we can see from Fig.4(a) that the number of the maximum run in the data must fall between 3 and 6 if we apply the 95% confidence interval or 2 and 7 for the 99% confidence interval.

(a) $h=1.60$

(b) $h=2.03$

Table-3 Measured runs of wave height in a numerical simulation ($h \geq 1$)

length	total	frequency	eq.(1)
1	22	0.44	0.467
2	10	0.20	0.249
3	6	0.12	0.133
4	3	0.06	0.071
5	4	0.08	0.038
6	1	0.02	0.020
7	0	0	0.011
8	3	0.06	0.006
9	1	0.02	0.003

Example 4 (verification of the experiment)

Table-3 shows the measured runs of wave height which exceed the mean wave height ($h_t=1$) obtained in the numerical simulation of the Pierson-Moskowitz spectrum. Figure 6 shows the comparison of data and the theoretical probability distribution of the run (eq.1). The agreement between the data and eq.(1) in the region $\ell \leq 4$ is fairly good. However, the verification of eq.(1) in the region $\ell \geq 5$ is difficult due to the fluctuation of data. This is mainly due to the insufficient amount of data. Instead of making a long measurement to obtain a sufficient amount of data, the following verification for the data is possible applying the ordered statistics explained so far. White circles in Fig.7 show the run of wave height in descending order from its 1st through 6th maximum values which are listed in Table-3. Two solid curves show the limit for the 95% confidence region given by eq.(31). Judging from the figure, the distribution has a statistical bias to the larger side.

Fig.6 Probability distribution of the run of high waves ($h \geq 1$)

Fig.7 Ordered maximum runs and the limit for the 95% confidence regions

5. SUMMARY AND REMARKS

The probability distribution of the maximum run of wave height for the irregular sea waves is introduced theoretically. The mean of the run and its approximations are also introduced and the changes with respect to the number of runs for different h_t are shown in the figure. The probability distributions for the 2nd maximum, 3rd maximum and further maximum runs and their mean values are also introduced. The confidence regions for the above means are introduced, although the definition for l is extended into real numbers and the traditional confidence coefficients of 95% and 99% are applied. (We may have to introduce confidence coefficients which are effective in coastal engineering problems.)

CHAPTER 49

SOME RESULTS FROM THE LABRADOR SEA EXTREME WAVES EXPERIMENT

Søren Peter Kjeldsen¹⁾
Harald Elias Krogstad²⁾
Richard Bjarne Olsen²⁾

ABSTRACT

The Labrador Sea Extreme Waves Experiment (LEWEX), is an international basic research programme concerned with full-scale measurements, analysis, modelling and simulation in test basins of 3-dimensional seas. The research is carried out in order to assess the significance of 3-dimensional sea states in engineering applications. The first phase of the programme full scale wave measurements in the North Atlantic Ocean was performed at a site and time that had a high probability of encountering severe sea states.

The present publication shows examples of measured bi-modal directional sea spectra obtained with the WAVESCAN buoy and directional sea spectra measured with an airborne Synthetic Aperture Radar (SAR). Directional spectra of gravity waves are obtained with the SAR both in open waters and below an ice cover. Further work is needed in order to verify SAR-measurements with in-situ observations. In-situ measured directional spectra are also compared with hindcast spectra from the 3G-WAM model. Hindcast significant wave heights were found to be lower than the in-situ measurements.

1. INTRODUCTION

The Labrador Sea Extreme Waves Experiment (LEWEX) is a large scale international research programme currently underway with participation from United States, Canada, Norway, Netherlands, France, West Germany, Spain and the United Kingdom. LEWEX is supported by a total of 17 research institutions from these countries, and has a variety of resources available for its activities (see BALES, BEAL and FREEMAN, 1987). The first phase of the LEWEX-programme full scale sea trials was successfully performed 9-27 March 1987. Fig. 1 shows the location of the experiment offshore the great banks of Newfoundland along with the positions of vessels, aircrafts and

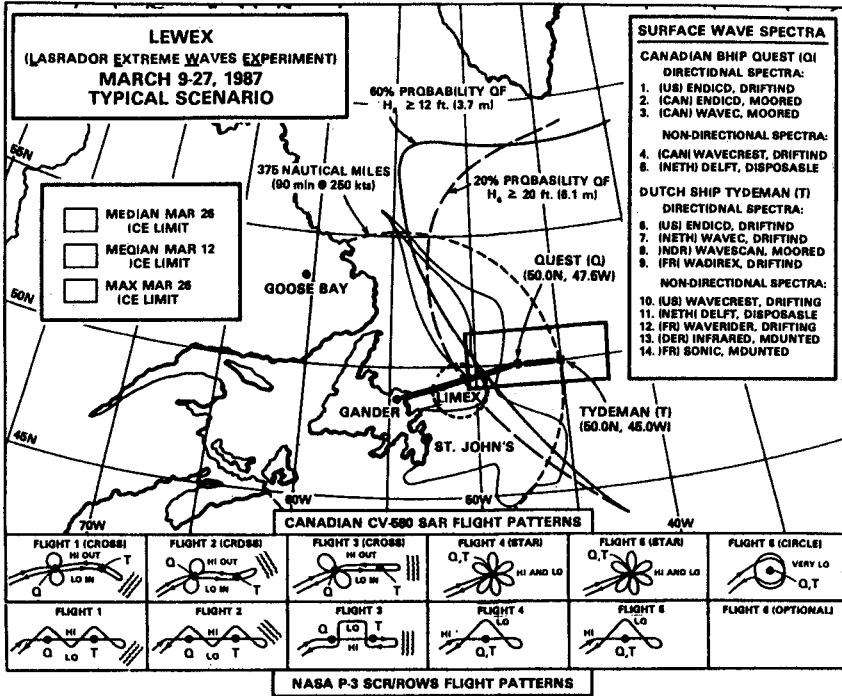

Fig. 1 LEWEX (Labrador Extreme Waves Experiment) March 9-27, 1987, typical scenario. Measurements of directional wave spectra were made with buoys as listed in the upper right corner and with the following airborne instruments: Synthetic aperture radar SAR, Surface Contour radar SCR, Radar Ocean wave spectrometer ROWS. (From BALES, BEAL and FREEMAN 1987).

participating in-situ and airborne instruments for directional wave measurements. Field measurements were supplemented with 9 numerical wave models developed for forecast and hindcast purposes. Two of these are global models. The LEWEX field activities were coordinated with a large marginal ice zone experiment LIMEX (Labrador Ice Margin Experiment) see (BHOGAL et al., 1987). Altogether, nearly 350 people have been involved in the planning, preparation and field work associated with these two experiments. The field experiment is now being followed up with a comprehensive data analysis, comparison of results as well as a reconstruction of selected measured sea states in the advanced 3-dimensional Ocean Wave Basin at MARINTEK, Norway.

The present paper which contains only a limited number of examples of results, shows directional bi-modal sea states obtained with the WAVESCAN buoy and examples of directional spectra obtained with SAR in open waters and below ice-covers. Finally, the paper contains a comparison between the 3G-WAM model and in-situ measurements for a bi-modal sea state.

2. SCOPE AND OBJECTIVES OF LEWEX

The major aim of the LEWEX-project is to evaluate the applicability and usefulness of directional wave data for engineering design. The largest responses in terms of motion of floating structures and associated sea loads are not always encountered in the most extreme sea state (see BALES, 1987). It turns out that less severe crossing seas in some cases lead to larger responses. Bi- and tri-modal directional seas were fairly common during LEWEX and even four modes were observed in a few cases. However, none of these sea states represent really heavy seas.

The performance of the various wave directional instruments under such complicated conditions is not well known. Therefore, one of the main scientific objectives of the LEWEX project is to recommend/identify new procedures where existing techniques of measurement or analysis are inadequate. A series of measurement systems for directional seas were used during the experiment:

- Moored oceanographic buoys: ENDECO, WAVESCAN, WAVEC.
- Freely floating oceanographic buoys, WAVEC, WADIREX, ENDECO.
- Shipborne navigation radar connected to a bow-mounted wave gauge.
- The NASA Surface Contour Radar (SCR).
- The NASA Radar Ocean Wave Spectrometer (ROWS).
- The CCRS' C-band Synthetic Aperture Radar (SAR).

In addition, a large number of drifting buoys were deployed for measurements of one-dimensional frequency spectra. From the measurements it was possible to determine the capability of the airborne remote sensing radars (SCR, SAR and ROWS) for estimation of the directional wave properties over a variety of sea states.

A second major aim of the LEWEX-project is to compare various idealized wave models and operational wave forecasts with observations. In particular, the LEWEX analysis intend to assess the relative performance of the recently developed "third-generation" (3G-WAM) wind wave model against earlier first and second generation

models. The 3G-WAM model incorporates superior physics over all of its predecessors at the expense of a significant increase in computational demands. The 3G-WAM model is most likely to exhibit its superiority in a complex, rapidly-changing sea state, as may occur associated with a major storm or frontal passage. No less than 9 operational wave forecast models have been run in hindcast mode for the LEWEX measurement period using common wind fields. One is thus able to assess the adequacy of directional wave estimates derived from various first, second and third generation wave forecast models in realistic complex sea states, and in situations for which a pre-existing wave field is likely to influence new wave growth. A final important objective of LEWEX is to examine the penetration of waves into the ice pack in cooperation with the Labrador Ice Margin Experiment, LIMEX, as shown in section 4.

3. EXAMPLES OF RESULTS - IN-SITU DIRECTIONAL WAVE MEASUREMENTS

The WAVESCAN metocean data acquisition buoy is shown in Fig. 2. It was first deployed from "Tydeman" at (50.0°N, 45.0°W) on 14 March 0345Z, see Fig 1. The water depth at the site was 3955 m. The buoy remained in this position until 18 March 2110Z. The buoy was then recovered and moved to (50.0°N, 47.5°W) where it remained from 19 March 0950Z to 20 March 1835Z. The buoy was finally deployed using a drag anchor for two periods between the 23 and 25 March. Data was recorded every 90 minutes throughout the experiment. During such operations, the buoy is checked daily by means of the ARGOS surveillance system. A pre-selected set of wave and meteorological parameters as well as various housekeeping data are transmitted to shore via ARGOS.

The directional analysis is carried out on the time series after the pitch/roll series have been rotated into the north-east reference system using the wave compass series. A Fast Fourier Transform is carried out on each of the time series and the resulting discrete Fourier transform of the heave series is compensated for by the manufacturer's transfer function. Similarly, the discrete Fourier transforms of the slope series are corrected for the buoy's hydro-mechanical behaviour which exhibits a response similar to a forced linear oscillator with eigenfrequency, f_0 , and damping ratio, λ . For WAVESCAN, $f_0 = 0.43$ Hz and $\lambda = 0.11$. The nine possible auto- and cross-spectra are computed from 2048 data point/1Hz time series and smoothed using a moving average over 16 adjacent frequencies giving spectral estimates with 32 degrees of freedom. The directional wave spectrum may be expressed as:

$$E(\theta, f) = S(f) D(\theta, f) \quad (1)$$

where S is the one-dimensional frequency spectrum and D is the directional distribution:

$$D(\theta, f) = \frac{1}{2\pi} + \frac{1}{\pi} \sum_{n=1}^{\infty} \{a_n(f) \cos n\theta + b_n(f) \sin n\theta\}, \quad (2)$$

and $\int_0^{2\pi} D(f, \theta) d\theta = 1$. The Fourier coefficients a_1 , b_1 , a_2 and b_2

Measured Variable	Sensor Type and Manufact.	Measuring Technique	Sensor Location	Range	Accuracy
Waves: Heave Pitch Roll	Datwell Hippy 40 or 120	Double integrated accel. Signal Magnetic inclinometer	Near the buoy's COB	± 10 m $\pm 90^\circ$ $\pm 90^\circ$ ± 10 m/s ²	$< 3.0\%$ $< 0.5\%$ $< 0.5\%$ $< 3.0\%$
Wind direction	Wind vane	Vector averaged over a 10 min.	3.7 m above sea level	0-360°	$\pm 4^\circ$
Wind Speed	Cup Anemometer B&G MOD 152	Vector averaged over a 10 min.	3.7 m above sea level	0-90 knots	$\pm 4\%$
Pressure	Monolithic AEB80 ANE		3.7 m above sea level	920-1070 mbar	± 0.5 mbar
Air temperature	Platinum		3.7 m above sea level	-40°C - +45°C	$\pm 0.4^\circ$
Sea temperature	Thermistor Aandersaa 1229		0.3 m above sea level	-4°C - +30°C	$\pm 0.2^\circ$
Compass	Fluxgate	Fluxgate DIGICOURSE 101E		0° - 360°	$\pm 1^\circ$
Internal Temperature		Transducer LM 235		-40°C - +125°C	$\pm 1^\circ$

Fig. 2 The WAVECAN metocean data acquisition buoy with instrumentation. (From KROGSTAD 1987).

are defined as follows (LONG, 1980):

$$a_1 = Q_{HE}/(C_{HH}(C_{EE} + C_{NN}))^{1/2} \quad (3)$$

$$b_1 = Q_{HN}/(C_{HH}(C_{EE} + C_{NN}))^{1/2} \quad (4)$$

$$a_2 = (C_{EE}-C_{NN})/(C_{EE}+C_{NN}) \quad (5)$$

$$b_2 = 2C_{EN}/(C_{EE} + C_{NN}) \quad (6)$$

In these relations, C denotes the co-spectrum and Q the quad-spectrum and the indices H heave, N slope in northerly direction and E slope in easterly direction. The main directional parameters are mean wave direction, $\theta_1(f) = \arctan(b_1/a_1)$, and circular standard deviation $\sigma_1 = 2(1-(a_1^2 + b_1^2))^{1/2}$.

A full directional estimate $D(\theta, f)$ based on a_1 , b_1 , a_2 and b_2 is the maximum entropy (MEM) spectral estimate (LYGRE and KROGSTAD, 1986):

$$D(\theta, f) = \frac{1}{2\pi} \left(1 - \phi_1 c_1^* - \phi_2 c_2^* \right) / \left(1 - \phi_1 e^{-i\theta} - \phi_2 e^{-2i\theta} \right)^2 \quad (7)$$

where

$$\phi_1 = (c_1 - c_2 c_1^*) / (1 - |c_1|^2) \quad (8)$$

$$\phi_2 = c_2 - c_1 \phi_1, \quad (9)$$

$$c_1 = a_1 + ib_1 \quad (10)$$

$$c_2 = a_2 + ib_2 \quad (11)$$

c^* is the complex conjugate of c . An example of a bi-modal wave number spectrum is shown in Fig. 3. The outer circle corresponds to a wave number, $k=2\pi/L=0.01m^{-1}$, while the inner circle corresponds to $k=0.005m^{-1}$. The energy scale is linear. The plot is oriented with North at the top and shows the direction towards which the waves are travelling. The observed wind direction is indicated with an arrow. The directional spectrum shows one wave system travelling towards the north in alignment with the prevailing wind direction and another system coming in as a swell and travelling nearly perpendicular to the first system towards west. The corresponding one dimensional frequency spectrum is shown to the right. The one-dimensional spectrum is not, however, bi-modal and the superiority and necessity of a complete directional resolution is clearly demonstrated.

Fig. 4 shows the development of two swell systems with nearly opposing directions at (50°N, 47.5°W). The time interval between the displayed spectra is 1.5 hour. Finally, Fig. 5 shows an example of directional sea spectra collected in the Gulf stream where wave-current refraction will be important. These measurements were obtained at (43°N, 55°W) where a very strong current shear was detected. At this position the cold Labrador current coming from the north

Fig. 3 Left, example of bi-modal directional wavenumber spectrum measured at grid point 1, on 16th March at 0000Z. Outer circle $k=0.01\text{m}^{-1}$, inner circle $k=0.005\text{m}^{-1}$. Right, the corresponding one dimensional frequency spectrum.

Fig. 4 Examples of development of two swell systems with nearly opposing directions at grid point 2, on 20th March at 0600Z, 0730Z, 0900Z, 1030Z.

Fig. 5 Examples of wave-current refraction of the directional sea spectrum observed in the current shear in the Labrador current and the Gulf Stream at 55°W , 43°N , on 24th March at 0600Z, 0730Z, 0900Z, 1030Z.

east encounters the warm Gulf Stream coming from the south west. In this case the buoy was operated with a drag anchor and moved through the current shear. At least 3 individual wave systems can be identified in the observed directional spectra. Propagation of swell from this area may be influenced by strong currents. Such an influence shall be taken into account in wave models.

4. EXAMPLES OF RESULTS FROM THE C-BAND SAR

Part of Canada's participation in the LEWEX experiment was to fly an airborne Synthetic Aperture Radar (SAR), belonging to the Canada Centre for Remote Sensing. The radar operates in the C-band, and is designed, among other things, for research work related to the European ERS-1 and Canadian RADARSAT satellites, planned to be launched in 1990 and 1994, respectively. The CCRS Convair 580 C-band SAR was flown operationally for the first time during LEWEX. It is a digitally controlled radar, with a digital recording system, and a sophisticated real time processor. Motion compensation is carried out in real time, using output from the inertial navigation system to control the antenna drive and to perform digital corrections to the in-phase and quadrature data before processing and recording. In addition to recording the real time processed data, raw signal data may also be recorded, allowing post-flight ground processing. A more detailed description may be found in (LIVINGSTONE et al. 1987).

The SAR was flown on 6 dedicated wave flights during the experimental period, in addition to 4 ice mapping flights for LIMEX, which took place further west in the same period. Fig. 6 (left) shows an image from the first flight on March 13 during the transit from Gander to "Quest"'s location, when waves were observed to propagate from the open water into the ice. Although we do not have ground truth data for this location, the image provides a very interesting situation for studying mechanisms of SAR imaging of ocean surface waves. SAR imaging of oceans waves is widely discussed in the literature, and a full understanding of all the mechanisms leading to SAR detection of ocean waves has not been reached at present. The imaging of waves propagating azimuthally, or along-track, is a particular point of discussion. The effects of scene motion may be divided into coherent and non-coherent classes. The most important coherent effects include velocity bunching, acceleration defocus and coherence time limitations. Non-coherent effects include scanning distortion and look mis-registration. It is important to understand the scene motion effects when interpreting SAR imagery and information, such as directional wave spectra. More detailed discussions may be found in the literature, e.g, (RANEY 1985), (RUFENACH and ALPERS 1981), ALPERS, ROSS and RUFENACH (1981), (RANEY and VACHON (1988), (HASSELMAN et. al. 1985). One of the limiting factors in imaging azimuthally travelling waves is the maximum available scene coherence time. This is often determined by estimating the target decorrelation time scale. For open water, where Bragg scattering is the dominant mechanism this is dominated by the wavelengths of the order of cm for C-band. For ice covered waters, however, the Bragg length waves are effectively filtered out and other back-scatter mechanisms dominate, providing the opportunity to study other effects, such as the velocity bunching mechanism and the look-misregistration.

Fig. 6 (left) shows a SAR scene from the marginal ice zone recorded 13th of March. The waves are propagating from the open water into the ice. Mechanisms contributing to the modulation of the image intensity could primarily be either tilt modulation or velocity bunching, or a combination of both. However, if we consider the variation of cross-section with incidence angle, this varies continuously from near nadir to more than 70 degrees. In the image, the average of this variation is compensated for, along with range and antenna pattern effects, through a real-time Sensitivity Time Control (STC). Removing the incidence angle component of the correction, averaging an ice covered portion of the image in the azimuth direction, and scaling the resulting curve with scatterometer data also acquired from the CV-580 during the experiment, we end up with a cross-section variation with incidence angle of 0.24 dB/degree in the midswath. In the same part of the image, wave image contrast was measured to 8.3 dB. Combining these two figures, we find that if tilt modulation were to be the only mechanism contributing to the wave imaging, a significant wave height of 20 m would be required, which is far higher than any wave observation reported in the area on this day. Ocean Data Gathering Program (ODGP) wave model forecasts actually predicted 3.4 m significant wave height. Velocity-bunching models in the literature (e.g. ALPERS and RUFENACH 1979) predict very narrow peaks in wave pattern image intensity. In examining the image, we find that the wave pattern in the ice, indeed has this character. The open water wave pattern, however, is somewhat broader but this could also be due to reduced resolution caused by scene coherence time limitations. Propagation of wave energy below the ice cover shall be considered in further developments of wave models.

Fig. 6 (right) shows examples of image spectra computed from the 512x512 pixel squares, at near, mid and far range for waves in ice and waves in open water. SAR image spectra will always be symmetric and the interpretation of wave direction has to rely on in-situ measurements or hindcasts. The circles correspond to wavelengths $L = 50, 100$ and 200 m. The spectra from the ice-covered regions are notably more complex than the open water spectra which indicate a single dominant wave system in all 3 cases. This system is also apparent in the ice spectra, but in these there are also additional contributions. In particular, the near and mid-range cases indicate a shorter wavelength component at a different propagation angle, which is not evident in the open water spectra. The reason for the latter may be scene coherence time limitations. Alternatively, this mode may be an artifact of velocity bunching when imaging waves with a relatively slow platform velocity and the geometry of this example. Theoretical work is currently being carried out in order to examine this effect more closely (VACHON, 1988). An intercomparison of SAR and WAVESCAN spectra where the latter are modified for scanning distortion is reported in (KROGSTAD and OLSEN 1988).

5. COMPARISON WITH 3-G WAM MODEL

The third generation (3-G) WAM-model is a wave model developed by an international team of ocean wave scientist. The model takes the non-linear transfer between wave frequencies due to resonant four-wave interactions fully into account and is based on ideas

LEWEX March 13, 1987

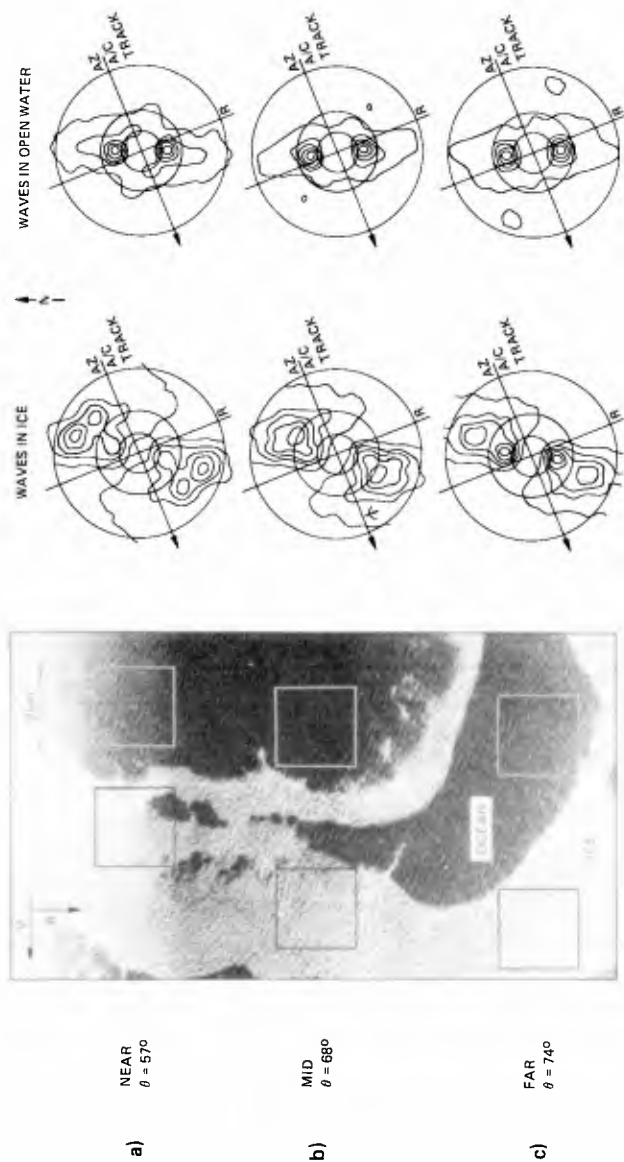

Fig. 6 Left: Real time SAR image of the ice margin obtained on March 13th. The six sub areas indicated were subjected to spectral analysis with the results appearing to the right. V is the aircraft vector, R is the range dimension, and θ is the angle of incidence. Right: SAR image spectra of the near, mid-, and far range subscenes extracted from the image. The contours of the spectra represent 10%, 30%, 50%, 70% and 90% of the peak spectral energy present. Circles correspond to wavelengths 50, 100 and 200 m.

developed at the Max Planck Institute for Meteorology (HASSELMANN et al. 1988). It is now operational at the European Centre for Medium-Range Weather Forecasts (ECMWF) and produces daily directional wave spectra over the entire globe. The model has been programmed in such a way that it can be interfaced with different wind field sources. In the LEWEX analysis a common wind field is used for all 9 wave models. However, in the present publication an alternative choice is made namely ECMWF-wind fields. The LEWEX-experiment is one of the opportunities that is available for calibration and tuning of the 3-G WAM model. Fig. 7 shows an example of hindcasted significant wave heights for the North Atlantic during the LEWEX-experiment. The position of the WAVESCAN buoy is also shown. On 16 March at 1200Z, a large storm with significant wave heights up to 10 m is present about 1130 nautical miles southwest of the WAVESCAN buoy and swell from the storm is propagating towards the buoy. Fig. 8 shows examples of directional spectra hindcasted with the 3-G WAM model and the corresponding directional spectra measured with the buoy. The directional spectra are shown in a plot with a logarithmic frequency scale. The circles correspond to frequency $f = 0.05, 0.10$ and 0.20 Hz. The wave energy scale is linear with constant contour. Wave direction is defined as the direction towards the waves are travelling. The wind direction is indicated by arrow.

On 16 March at 0600Z, the wind is weak and from SE. A swell is evident from the same direction. By 1200Z, the wind has increased and veered to NE. A secondary swell is now propagating out of the Labrador Basin travelling towards SE. At 1800Z a new wind-driven sea is evident, superimposed upon the two previously existing wave systems. This tri-modal sea is predicted by the 3G-WAM model, but the model overestimates the energy content in the swell travelling towards NW. On the 17th March the wind gradually turns to SE and SW, and increases again, see Fig. 9. There is a good qualitative agreement between measured and hindcasted spectra for this complex bimodal sea, although, the hindcast spectra appear to overestimate the SW swell travelling towards NE. The timing of the swell is important. The 16th at 0600Z the hindcast swell has not yet arrived at the buoy. It arrives by 1200Z and from that time there is a good qualitative agreement between bi-modal measured and hindcast directional spectra. There is also good agreement for the case shown on the 17th March. However, the hindcast significant wave heights are biased, and 20-30% lower in these examples than in the measurements. Further analysis and comparisons are ongoing.

6. CONCLUSIONS

1. - Results from the LEWEX-experiment indicate that some of the most important parameters for a proper description of directional sea states are the number of individual sea systems contained in the directional sea and their relative orientation. It is expected that directional spectra to be used in the future for engineering design will be more complex, and thus closer to realistic sea states. Thus, the demand that ocean basins be able to simulate more realistic directional sea states for engineering applications, will increase. A swell-corrupted wind sea is a quite common situation, as the LEWEX full scale directional wave measurements show.

2. - Validation of the capability of airborne and spaceborne (shuttle) SAR, SCR and ROWS to detect directional distributions of ocean gravity waves will be an important aspect of the LEWEX-programme. A method is suggested by (KROGSTAD and OLSEN 1988) for modifying in-situ data to provide spectra which are equivalent to those expected from an ideal airborne scanning instrument. Still much validation of results is needed in this area. In the future it is foreseen that global orbiting space shuttles and satellites will provide us with a large quantity of directional sea spectra covering all sea areas of the world. Such data should be assimilated into wave forecasting models.

3. - Significant wave heights hindcast with the 3G-WAM model were found to be 20-30% lower than in-situ measurements and measured swell components were somewhat delayed in time. Accuracy of wave forecasts/hindcasts will depend on accuracy of the chosen input wind fields.

4. - Propagation of wave energy below the ice cover shall be considered in further developments of wave models.

5. - Propagation of swell in this part of the North Atlantic may be influenced by strong currents, and such an influence shall be taken into account in wave models.

7. ACKNOWLEDGEMENTS

The LEWEX-project is organized within NATO as a multi-lateral scientific research programme. Two working groups are responsible for the performance of the LEWEX-project. These are RSG-1 and RSG-2. A list of participating scientists is found in (BALES, BEAL and FREEMAN 1987).

CHAPTER 50

On the Partition of Horizontal Momentum Between Velocity and Pressure Components Through the Transition Region of Breaking Waves

David R. Basco¹ and Takao Yamashita²

Abstract

When a water wave breaks, it undergoes a complicated interchange of total, depth integrated horizontal momentum between that part due to the velocity field and the part that can be assigned to the pressure distribution beneath the surface. This partition of total momentum for a strong, plunging breaker is described by a relatively crude model in which the horizontal velocity profile (over the vertical) is schematized in two layers and the pressure distribution is related to a hydrostatic distribution for the given water depth. An example calculation at four locations across the breaking transition region on a plane beach is utilized to demonstrate the principles of the model. The limitations of the approach which assumes momentum conservation in a reference frame moving with the wave celerity defined at the wave crest are presented, but await verification. The ultimate goal is a relatively simple model to predict the transition width of breaking waves (spillers, plungers and intermediate types) for plain and bar-trough beaches.

1.0 Introduction

Svendsen (1984) defined the wave breaking transition region as the distance from the break point (vertical free surface) to the transition point where the time-mean water surface changes from relatively level to an increasing slope (wave set-up). Figure 1 displays these two end points along with the plunge point (pp) and an intermediate point (ip) which shall be discussed later. At the transition point (tp), the bore-like wave with surface roller area (A) encompasses a trapped mass of fluid which is transported within the inner, surf-zone region on plane beaches.

A qualitative description of the transition region was presented by Basco (1985). The overturning, plunging jet pushes on the trough fluid ahead like a wave paddle to create the surface roller but is left behind as it generates a new, bore-like wave with completely new wave kinematics. A simple, empirically based transition zone model designed to match the Svendsen (1984) inner-region model was then presented by Basco and Yamashita (1986) at the 20th ICGE in Taiwan. The surface

²Instructor, Disaster Prevention Research Institute, Kyoto University Kyoto 611, Japan

Fig. 1 Schematic of Transition and Four Key Locations

Fig. 2 Growth of Surface Roller Area With Distance From Break Point (after Papanicolaou and Raichlen, 1987)

roller area $A(x)$ was speculated to increase linearly from zero at the plunge point to a value equal to $0.9 H^2$ at the transition point as suggested by Svendsen (1984). Fig. 2 from experimental data by Papanicolaou and Raichlen (1987) suggests that $A(x)$ varies nonlinearly as the squared distance from the plunge point to the place where $A \sim 0.9 H_b^2$. It is not clear however that these researchers used the same definition of surface roller area, A as first suggested by Svendsen (1984).

This paper extends these previous efforts by developing a quantitative model for the horizontal, total depth integrated momentum as partitioned between the momentum flux due to the velocity and the pressure induced momentum component. This is done in a reference frame moving with the wave celerity defined by the wave crest. Total, vertically integrated, horizontal momentum is conserved in this system.

Section 2 presents the general theory and discusses the limitations of the approach. Theoretical expressions are derived in Section 3 for the four locations in Fig. 1 and a general expression is formulated for any location. An example computation to demonstrate the plausibility of the formulations is then presented in Section 4. The paper concentrates on strong plunging breakers on a plane beach with the goal to develop relatively simple ways to predict the transition width. And, eventually to also model the transition width on a bar-trough profile where the surface roller grows and then decays rapidly as the wave "reforms" in the trough.

2.0 Theoretical Considerations

2.1 Steady Flow Momentum Balance. The vertically integrated, total horizontal momentum (m) per unit width and unit mass density (ρ) can be found from

$$m = \int_0^h \left[u^2(z) + \frac{1}{\rho} p(z) \right] dz \quad (1)$$

where z is the vertical coordinate from the floor ($z = 0$) to the free surface ($z = h$) and $u(z)$, $p(z)$ are the horizontal velocity and pressure distributions beneath the surface, respectively. From standard definitions of the volumetric flow rate per unit width (q), momentum correction coefficient (α), and a pressure correction coefficient (a) relative to hydrostatic pressure (e.g., see Chow, 1959, p. 32) this can be written

$$m = \alpha \left[\frac{q^2}{h} \right] + a \left[\frac{1}{2} \rho g h^3 \right] \quad (2)$$

or

$$m = m_v + m_p \quad (3)$$

so that total momentum is partitioned between the momentum flux part (m_v) and the pressure component (m_p). Four initial conditions are required to define m , namely the water depth (h), velocity magnitude ($v = q/h$), velocity profile (α) and pressure distribution (a).

For the classical hydraulic jump (Belanger, 1849), a uniform velocity profile ($\alpha = 1$) and hydrostatic pressure distribution ($a = 1$) are assumed both upstream and downstream of the surface roller. This reduces the problem to only two initial conditions and two unknowns so that together with the conservation of mass, a unique solution (the so-called sequent-depth equation) is possible for the downstream conditions. Madsen and Svendsen (1983) utilized a theoretical velocity profile for the flow reversal with depth through the surface roller and an empirical, vertical turbulent momentum exchange coefficient to theoretically derive the jump profile and jump length. Basco and Yamashita (1986, Fig. 6, p. 956) used this theory to present the partition of $m_v(x)$ and $m_p(x)$ across the jump. The surface roller, flow reversal causes $\alpha \gg 1.0$ through the jump and results in nonlinear distributions of $m_v(x)$ and $m_p(x)$ components even though $a(x) = 1$ is taken as a first approximation.

2.2 Unsteady Flow Momentum Conservation. The integral, control volume definition of linear momentum conservation for unsteady flow can be written in vector terminology (\vec{V} is the vector velocity field)

$$\int_V \frac{\partial(\rho \vec{V})}{\partial t} dV + \int_s (\rho \vec{V}) \vec{V} \cdot d\vec{s} = \Sigma \vec{F} \quad (4)$$

the first term (LHS) is the unsteady flow contribution over the control volume (V) and the second is the momentum flux through the control surface (s). The RHS is the sum of all external forces (F) responsible for the changes taking place on the LHS.

In this paper, we make the unproven assumption that the unsteady, time-derivative term on the LHS is small relative to the other terms in the momentum balance. Therefore we neglect the time-derivative term in this paper. For a breaking/broken water wave with dominant flow direction parallel to the bottom, the momentum balance in this direction is then given by Eqn (1) if we also neglect the boundary shear stress. And, if we operate in a moving coordinate system.

2.3 Non-accelerating Coordinate System. We can perform a Galilean transformation of our momentum conservation equation by moving our control volume at constant speed, i.e., by using a non-accelerating coordinate system. To remain phase locked with the wave crest we can use the wave propagation celerity as defined by the crest.

In this paper, we make the experimentally demonstrated assumption that the breaking/broken wave celerity through the transition region is approximately constant (see e.g., Basco, 1985, Fig. 4, p. 175).

2.4 Time-averaged Momentum Balance. Time-averaging Eqn (1) and then subtracting the hydrostatic pressure force measured from the mean water surface ($\bar{\eta}$) for a water wave produces the wave-induced momentum thrust or radiation stress. Across the transition region, by definition, $\bar{\eta}$ is constant so that if we again neglect the bottom shear stress, the radiation stress must also be constant based on the time-averaged momentum balance. One way for this to occur is for each phase-locked section of the breaking/broken wave moving through the transition to have constant total momentum. This gives added confidence to our assumptions cited above.

3.0 Transition Region Theory

3.1 Definitions. Consider the velocity profile $u(z)$ beneath a breaking wave as shown in Fig. 3 relative to a fixed reference frame. We schematize the velocity distribution into two major segments; (1) a crest region velocity $V_c(x)$ and (2) a trough region velocity $V_t(x)$ that act over $b(x)$ and $d(x)$, respectively. Note that one key feature of wave breaking is that the crest region and trough region absolute* velocities are in opposite directions.

It is useful to define the following dimensionless ratios using the wave crest celerity (c) as the reference velocity:

$$\lambda = \frac{V_c}{c} \quad (5)$$

$$\xi = \frac{|V_t|}{V_c} \quad (6)$$

therefore

$$\lambda\xi = \frac{|V_t|}{c} \quad (7)$$

The wave crest celerity for shallow water wave breaking is approximately

$$c^2 \approx gh_c \quad (8)$$

where h_c is the total water depth at the wave crest.

3.2 Moving Reference Momentum Balance. The counterpart of Eqn (1) for a control volume moving with speed (c) is

$$m^* = \int_0^h \left\{ [u(z) + c]^2 + \frac{1}{\rho} p(z) \right\} dz \quad (9)$$

or

$$m^* = m_v^* + m_p^* \quad (10)$$

where now total relative momentum (m^*) is partitioned into relative velocity (m_v^*) and pressure (m_p^*) components.

3.3 Schematized Transition - Strong Plunging Breaker. Using the qualitative model and ideas presented in Basco (1985), we schematically depict the velocity and pressure distributions for a strong, plunging breaker on a plane beach in Fig. 4. The crest velocity begins to exceed the wave celerity ($\lambda \geq 1$) at the break point and continuity results in $\lambda \gg 1$ at the plunge point for a strong plunging jet. At this point, the surface roller begins to form ($A \geq 0$) and grows in size as the plunging jet slows down ($\lambda < 1$) and exchanges its momentum through turbulent shear stresses with the trough fluid below. The overturning jet of a

*Absolute when referenced to a fixed (Eulerian) observer.

Fig. 4 Schematized Velocity and Pressure Distributions Across Transition Region (following qualitative model of Basco, 1985)

Define

$$\lambda \equiv \frac{V_c}{C}$$

$$\lambda \xi \equiv \frac{|V_t|}{C}$$

$$\xi \equiv \frac{|V_t|}{V_c}$$

$$C^2 = gh_c$$

Fig. 3 Schematized Horizontal Velocity Distribution Beneath Crest Region of Breaking Wave

breaking wave can be seen to perform two primary tasks in the transition region, namely:

- (1) to create a surface roller, with trapped mass of fluid that propagates with the wave celerity, and
- (2) to reverse the direction of the trough velocity from that opposing the crest, to that in the same direction as the particles in the surface roller.

At the transition point, or end of the transition region, the velocity profile beneath the crest is that of a propagating bore (Svendsen, 1984).

The corresponding pressure distribution changes are also shown in Fig. 4. Streamline curvature causes the pressure to remain less than hydrostatic ($a < 1$) through the break point. The pressure within the plunging jet is essentially zero if we assume it behaves as a free jet so that the pressure falls to essentially that approximated by hydrostatic pressure in the trough fluid. The pressure distribution then rises again to reach full hydrostatic pressure ($a = 1$) at the transition point.

These schematic ideas are translated into quantifiable relations at four representative locations within the transition region.

(i) Break Point (bp)

Fig. 5 depicts the absolute velocity structure ($\xi < 1$) and assuming $\lambda = 1$ ($V_c = c$), the velocity distribution for an observer moving with the wave crest, i.e., the relative velocity is also shown acting over the depths indicated. The velocity momentum (m_v^*) is then given by

$$m_v^* = (V_t + c)^2 d_t = [(\lambda\xi)c + c]^2 d_t = c^2(\lambda\xi + 1)^2 d_t \quad (11)$$

and is taken here to act over the depth (d_t) which is essentially the trough depth for a strong plunging breaker. Using Eqn (8) for c^2 and multiplying by unity (h_c/h_c) gives

$$m_v^* = \left[\frac{dt}{h} \right] (\lambda\xi + 1)^2 gh_c^2 \quad (12)$$

The first two terms in parentheses are dimensionless so that the last term (gh_c^2) gives the physical scale to the momentum and/or can be used to normalize the equation.

The pressure related momentum is simply

$$m_p^* = (a) \left[\frac{1}{2} gh_c^2 \right] \quad (13)$$

so that the total, relative momentum at the break point (m_{bp}^*) becomes

$$m_{bp}^* = \left[\left[\frac{dt}{h} \right] (\lambda\xi + 1)^2 + \frac{1}{2} a \right] gh_c^2 \quad (14)$$

Fig. 6 Plunge Point - Absolute and Relative Velocities

Fig. 5 Break Point - Absolute and Relative Velocities

Fig. 8 Transition Point - Absolute and Relative Velocities

Fig. 7 Intermediate Point - Absolute and Relative Velocities

Four quantities must be specified [(d_t/h_c) , ξ , a , and h_c] to define m_{bp}^* if we assume $\lambda = 1$ at the break point.

Using the trough relative Froude number (F_t^*) as a measure of the strength of the breaking wave defined as (Stive, 1984)

$$(F_t^*)^2 = \frac{(V_t + c)^2}{gd_t} \quad (15)$$

this becomes at the break point

$$(F_t^*)^2 = (\lambda\xi + 1) \left[\frac{h_c}{d_t} \right]^{1/2} \quad (16)$$

or combining Eqn (12) and (16) we have

$$(F_t^*)^2 = \frac{m_v^*}{gh_c^2} \left[\frac{h_c}{d_t} \right]^2 \quad (17)$$

so that we need only two quantities (d_t/h_c and ξ) to specify the incoming relative Froude number if we again take $\lambda = 1$ at the wave breaking point.

(ii) Plunge Point (pp)

Now, $\lambda > 1$ ($V_c > c$) and again taking $\xi < 1$ as depicted in Fig. 6 with V_c acting over a contracted, free jet width $b(x)$ with $p = 0$ gives

$$m_v^* = \left[\frac{d_t}{h_c} (\lambda\xi + 1)^2 + \frac{b(x)}{h_c} (\lambda - 1)^2 \right] gh_c^2 \quad (18)$$

with the plunging jet now contributing to the relative momentum as given by the second term within the brackets.

With the pressure zero in the overturning jet, the pressure momentum coefficient a becomes

$$a = \frac{1/2gd_t^2}{1/2gh_c^2} = \left[\frac{d_t}{h_c} \right]^2 \quad (19)$$

if we assume the streamlines within the trough are relatively flat to create a hydrostatic pressure distribution. This then results in

$$m_p^* = \left[\frac{1}{2} \left[\frac{d_t}{h_c} \right]^2 \right] gh_c^2 \quad (20)$$

when the wave crest height h_c is used as reference. Combining gives for total relative momentum at the plunge point (m_{pp}^*)

$$m_{pp}^* = \left[\left[\frac{d_t}{h_c} \right] (\lambda\xi + 1)^2 + \frac{b(x)}{h_c} (\lambda - 1)^2 + \frac{1}{2} \left[\frac{d_t}{h_c} \right]^2 \right] gh_c^2 \quad (21)$$

Comparing Eqn (14) at the break point and (21) we see that if total, relative momentum is conserved, and when the first term within the brackets also remains relatively unchanged, then the added momentum of the overturning jet is balanced by the decreased pressure momentum within the trough. Four quantities [d_t/h_c , b/h_c , λ , and h_c] must again be specified to calculate m_{pp}^* if we now also assume that ξ remains the same as at the break point.

(iii) Transition Point (tp)

Now lets move to the end of the transition region and consider the transition point (t_p) as depicted in Fig. 8. We here define the velocity in the trapped surface roller as V_s to distinguish it from that within the plunging jet (V_c) that is slowing down and being left behind [$\lambda \rightarrow 0$, $b \rightarrow 0$]. The surface roller area (A) grows as shown in Fig. 2 and consequently so does the thickness of the trapped surface roller (e).

The relative velocity momentum becomes

$$m_v^* = \left[\frac{d(x)}{h_c} (\lambda\xi - 1)^2 \right] gh_c^2 \quad (22)$$

and the fact that the trough velocity V_t is now in the same direction as the wave celerity produces the negative sign within the bracketed term. This translates into a decrease in relative importance in the velocity component of the total momentum.

The pressure component must therefore increase and we take $a = 1$ to give full hydrostatic pressure as a first approximation, or

$$m_p^* = \frac{1}{2} gh_c^2 \quad (23)$$

so that the total relative momentum at the transition point (m_{tp}^*) becomes

$$m_{tp}^* = \left[\frac{d}{h_c} (\lambda\xi - 1)^2 + \frac{1}{2} \right] gh_c^2 \quad (24)$$

We again need four quantities [d/h_c (or e/h_c), λ , ξ and h_c] to compute m_{tp}^* .

(iv) Intermediate Point (ip)

This is obviously the most complicated region between the plunge and transition points (see Fig. 4). The plunging jet velocity slows down ($V_c < c$) as the surface roller moving with the phase speed ($V_s = c$) expands from $e = 0$ at the plunge point to e at the transition point where $A = 0.9 H_b^2$. The most important physical factor is the reversal in direction of V_t so that the $(\lambda\xi + 1)$ term becomes $(\lambda\xi - 1)$. Also V_t acts over an expanding width $d(x)$ as $b(x) \rightarrow 0$ which is a consequence of the turbulent mixing between the jet and trough fluids. Fig. 7 depicts both absolute and relative velocity distributions at an intermediate point where the trough velocity is still opposing the wave celerity. In general, the velocity momentum can be written

$$m_v^* = \left[\frac{d(x)}{h_c} (\lambda \xi \pm 1)^2 + \frac{b(x)}{h_c} (\lambda - 1)^2 \right] g h_c^2 \quad (25)$$

and the pressure momentum

$$m_p^* = \left[\frac{1}{2} a \right] g h_c^2 \quad (26)$$

so that the total relative momentum at an intermediate position becomes

$$m_{ip}^* = \left[\frac{d(x)}{h_c} (\lambda \xi \pm 1)^2 + \frac{b(x)}{h_c} (\lambda - 1)^2 + \frac{1}{2} a \right] g h_c^2 \quad (27)$$

Eqn (27) reduces Eqn (14) at the break point, to Eqn (21) at the plunge point and to Eqn (24) at the transition point when the appropriate assumptions are made. Consequently it is also the general expression for total relative momentum anywhere within the transition region.

In general, six quantities [d/h_c , λ , ξ , b/h_c , a , h_c] are needed to use Eqn (27). Two additional expressions can be $e(x)$ as related to $A(x)$ and some relation for $b(x) \rightarrow 0$ in the overturning jet along with the fact that $e(x) + b(x) + d(x) = h_c$.

4.0 An Example Computation

Consider a strong plunging breaker on a plane beach with crest height h_c of 13.5 ft (4.1m) at the instant of breaking. The water depth in the trough, immediately ahead is about one-half this depth ($d_t/h_c = 0.5$) and the trough velocity is about 20% of the crest velocity ($\xi = 0.2$, Stive, 1984). The situation is schematized in Fig. 9 and summarized in Table I. Assume also that at the instant of breaking (front wave face is vertical) the streamline curvature is such that the pressure coefficient a is 0.6. Using Eqn. (14), the relative velocity momentum, m_v^* is calculated to be $4221 \text{ ft}^3/\text{sec}^2$ ($120 \text{ m}^3/\text{s}^2$) and the pressure momentum, m_p^* is $1759 \text{ ft}^3/\text{sec}^2$ ($49 \text{ m}^3/\text{s}^2$) resulting in a total relative momentum, m^* of $5980 \text{ ft}^3/\text{sec}^2$ ($169 \text{ m}^3/\text{sec}^2$). In other words, the total momentum is about $6000 \text{ ft}^3/\text{sec}^2$ of which the initial partition at breaking results in 71 percent due to velocity and 29 percent due to pressure.

From Eqn (16), the relative trough Froude number, F_t^* is 1.7. This value would indicate a strong plunging breaker (spilling breakers have much lower values) but a weak bore or hydraulic jump. The fluid flow in the trough in the relative, moving coordinate system is supercritical.

As the wave overturns, the crest height (h_c) decreases. The example shows h_c values (col 3) of 13.1 ft (4.0m) at the plunge point, 12.7 ft (3.9 m) at the intermediate point, and 12.3 ft (3.7m) at the transition point or end of the transition region. These values were estimated for this example although they also could have been calculated if the total relative momentum m^* was assumed constant at $6000 \text{ ft}^3/\text{sec}^2$.

The example shows that using these h_c values and the other given conditions which are all plausible and or referenced magnitudes, that

Transition Point Eqn (24)	8,12 12.3 (3.7)	-	$\lambda \xi = 0.1$ [9]	0.1 [10] (assume)	1.0 (assume)	3553 (101)	0	3553 (59%)	2433 (41%)	5986 (169)	Velocity Still Dominates But to Less Extent	

the partition of momentum changes through the transition. At the plunge point, we have taken the value of $\lambda\xi$ the same as at the break point but increased λ to over 2 as demonstrated numerically by Cokelet (1976) and experimentally by Kjeldsen (1984). The result is more velocity momentum with m_v^* now being $5300 \text{ ft}^3/\text{sec}^2$ ($150 \text{ m}^3/\text{s}^2$) or almost 89 percent of the total. And, a full 22 percent of the total is found in the jet momentum. The pressure component drops to only $960 \text{ ft}^3/\text{sec}^2$ ($20 \text{ m}^3/\text{sec}^2$) which is 11 percent of the total m^* of $5990 \text{ ft}^3/\text{sec}^2$ ($170 \text{ m}^3/\text{s}^2$).

At the intermediate section, the pressure begins to recover with m_p^* now $1998 \text{ ft}^3/\text{sec}^2$ ($57 \text{ m}^3/\text{s}^2$) or 33.4 percent. The velocity momentum, m_v^* has dropped to $3978 \text{ ft}^3/\text{sec}^2$ ($113 \text{ m}^3/\text{s}^2$) or 66.6 percent and of this amount, only $73 \text{ ft}^3/\text{sec}^2$ ($2 \text{ m}^3/\text{sec}^2$) remains in the crest region due to the plunging jet. Clearly, the original, plunging jet momentum is decaying and being left behind.

At the end of the transition region, the pressure component (m_p^*) has now risen to $2433 \text{ ft}^3/\text{sec}^2$ ($69 \text{ m}^3/\text{s}^2$) or 41% of the total which is the highest across the entire region. Conversely, the relative velocity momentum, m_v^* is the lowest [$3553 \text{ ft}^3/\text{sec}^2$, ($101 \text{ m}^3/\text{s}^2$), 59 percent] since all the particles beneath the crest are now traveling in the same direction as the wave. The given conditions employed in these calculations were aided by experimental data found in Stive (1988) and Svendsen (1984). At the end of the transition region, the relative velocity momentum still dominates the pressure component but to a far lesser extent.

5.0 Summary

All of these values are summarized in Fig. 13 for the four "points" across the transition region. Smooth curves have been drawn in to demonstrate the momentum partition trends for this example. These results, although a delicate balance and sensitive to the individual values used for each given condition at each section, can be looked upon as somewhat indicative of the general trends that must be present, namely:

- (i) the velocity dominates in all cases and is largest at the plunge point of a strong, plunging breaker;
- (ii) the trough velocity is the key variable, and the physical processes present to reverse its direction dominate the transition region; and
- (iii) the pressure is secondary in all cases and is smallest at the plunge point, then recovers to attain its greatest influence at the end of the transition region.

For a strong, plunging breaker on a plane beach and within the limitations and assumptions made throughout, we have developed a crude, quantitative model of the relative momentum and its partition. The role of the plunging jet momentum is to (1) form a surface roller and (2) reverse the trough flow direction over the trough depth. It becomes quite apparent that the relative strengths of the plunging jet momentum and the trough momentum control the time and hence spacial extent over which this transition process takes place. At one extreme is a relatively rapid, short transition as in this example for the strong

Fig. 13 Summary of Example Computation Across Transition Region

plunger.

The opposite extreme is a weak spilling breaker. The small overturning jet at the crest is still present but barely discernable. It's role remains the same but the transition requires a wide distance for the full surface roller to form and for the trough flow to be reversed over the entire vertical depth.

However, in both extremes, the strength of the trough velocity is believed to be the key variable. In nature, at some beaches, we can simultaneously observe waves breaking on relatively plane sections, waves breaking on bars and reforming in the deeper trough regions and waves breaking in the swash zone right on the beach. In all cases, the strength of the return flow in the trough appears to control the entire process. Consequently, it is felt that future numerical and experimental research (both laboratory and field) on breaking waves should give greater emphasis to defining the character of the trough flow.

CHAPTER 51

A DIRECTIONAL PREDICTION MODEL OF WAVES WITH VARIABLE WIND

Juan R. Acinas

ABSTRACT.- A model of the response of the direction of the waves to changing winds is presented. First the theoretical results that associate an average direction of energy propagation to every wave component is introduced. From this model, numerical results are presented both by simulations of ideal wind veering situations and compared with field data taken from pitch and roll buoys.

1. INTRODUCTION

The wave generation as a response to action of wind variable in intensity and direction is still an open problem, where either the theoretical models or the numerical methods used for its forecasting and hindcasting require a proper validation based on strictly controlled wind and wave measurements.

This communication presents a theoretical model of the directional wave response, as well as numerical examples in ideal conditions and comparisons with field data taken from the Norwegian ODAP project.

The model allows us to associate an average direction of energy propagation to every spectral component, so that with a little additional computational effort we get a wave prediction method with analogous precision in the two dimensions of the spectrum; frequency and direction.

Numerical results are presented illustrating the general behaviour of the wave directional relaxation. The data available to the author backs up these results.

2. MODEL

The global mean direction Ω of the wave spectral density function $S(f,\theta) = S(f) \cdot D(f,\theta)$ due to the wind action depends on: The boundary and initial values of the wave field, the change in the directional shape of S , and the direct action of the wind. This effect has, in turn, two components; the energy contribution E_{Δ} , and the change in its directional distribution, J.R.Acinas (1987).

In this communication only the directional variation due to the energy E_{Δ} , is taken into account as a consequence of the wind action in a homogeneous wave field. Starting from the energy balance equations and the global average direction of the wave:

$$dS(f,\theta)/dt = G(f,\theta) \equiv \text{Source Function} \quad (1)$$

$$\Omega = \arctan \left(\int_0^{2\pi} \sin\theta \cdot S \cdot df \cdot d\theta / \int_0^{2\pi} \cos\theta \cdot S \cdot df \cdot d\theta \right) \quad (2)$$

Differentiating equation (2) and after some manipulations involving (1) and (2) the result is:

$$\frac{d\Omega}{dt} = \frac{-DI}{A^2 + B^2} \cdot \frac{1}{E} \cdot \frac{dE_{\Delta}}{dt} \quad (3)$$

with: $DI = (A_{\Delta}B - B_{\Delta}A)\cos\epsilon - (A_{\Delta}A + B_{\Delta}B)\sin\epsilon$
 A, B and A_{Δ}, B_{Δ} first order direction estimators of the total wave energy, E , and of the wind contribution, E_{Δ} .
 $A = \iint \cos\theta D(f,\theta) df d\theta$; $B = \iint \sin\theta D df d\theta$
 $S = (\theta_u - \Omega)$; $E = \iint S(f,\theta) df d\theta$

If we centre $D(f,\theta)$ around Ω , we obtain in general

$$\frac{d\Omega}{dt} = \left(\frac{A_{\Delta}}{A} \cdot \sin\epsilon + \frac{B_{\Delta}}{A} \cdot \cos\epsilon \right) \cdot \frac{1}{E} \cdot \frac{dE_{\Delta}}{dt} \quad (4)$$

and doing the same with the energy contribution, E_{Δ} we have

$$\frac{d\Omega}{dt} = \frac{A_{\Delta}}{A} \sin \delta \cdot \frac{1}{E} \cdot \frac{dE_{\Delta}}{dt} \quad (5)$$

If we consider, for example, spectral evolution according to the JONSWAP study, we obtain the global average direction of the wave (based on parameters which characterise its growth) by:

$$\frac{d\Omega}{dt} = \frac{A_{\Delta}}{A} \sin \delta \cdot \frac{E_{\Delta}}{E} \cdot \left(-4 \cdot \frac{dL f_P}{dt} + \frac{dL \alpha}{dt} + \frac{dLP}{dt} \right)_{\Delta} \quad (6)$$

with: $P = P(\gamma, \sigma) = \int_0^{\infty} x^{-5} \exp(-1.25/x^4) \cdot \gamma^y dx$
 $y = \exp(-((x-1)/\sigma)^2 / 2)$

The response of the wave direction Ω_c , of a spectral band (f_1, f_2) represented by the frequency, f_c and energy component E_c is similarly given by:

$$\frac{d\Omega_c}{dt} = \frac{A_{\Delta c}}{A_c} \sin \delta \cdot \frac{1}{E_c} \cdot \frac{dE_{\Delta c}}{dt} \quad (7)$$

Systematic application of this formulation is the basis of the development of a directional wave prediction model in which each spectral component has an associated mean direction of energetic propagation.

3. RESULTS

The model is illustrated both by simulations under ideal wind-veering situations (Figs. 1 and 2), and compared with measurements from the ODAP data analyzed by T. Audunson et al. (1981), Fig. 3.

Initial wind and wave conditions are assumed to be homogeneous and are used as input to a parametrical wave prediction model, (Acinas 1981).

Fig.1 Response of wave direction to a sudden change $\Delta\theta_u$, in wind direction. Wind velocity U , constant.

- a) Global mean wave direction response Ω , to $\Delta\theta_u = 10^\circ, 22.5^\circ$ and 45° . Initial peak frequency $f_{pi} = 0.2\text{Hz}$.
- b) As in a) but for $\Delta\theta_u = 45^\circ$ and $f_{pi} = .15, .2, \text{ and } .3\text{Hz}$. Response $\Omega_a(3/2f_p)$ and $\Omega_b(2/3f_p)$; $f_{pi} = 0.15\text{Hz}$.

Computation is carried out along characteristic lines and for easier comparison of results, $A_\Delta/A = 3.5$ has been used for all cases. This number comes from an empirical best fit with the ODAP data.

Inspection of the equations and results shows the following behaviour:

a) For the same initial wave field, the veering rate of Ω grows according to $\Delta\theta_u$.

b) For the same variation $\Delta\theta_u$, Ω grows faster with the largest f_p of the initial state.

c) For a given wave field, the direction Ω_a , of the high frequencies, $f_a > f_p$, responds in a quasi-instantaneous way to the variations of θ_u , and at a faster rate than the global direction.

On the other hand, low frequencies $f_b < f_p$ show a temporal delay in the response with lower response rate than the global direction.

Fig.2 Response of global, high and low frequency directions Ω , Ω_a and Ω_b , to changing wind (U, θ_w); $f_{pi} = .2\text{Hz}$.

a) (U constant, θ_w variable) b) (U variable, θ_w variable)

d) As the wave field grows towards FDW (fully developed wave spectrum) levels, the direction at all frequencies tends to align with that of the wind.

These results are in analogous with the theoretical-experimental results suggested previously by several authors; D.E. Hasselmann et al. (1980), H.Gunther et al (1981), T.Audunson et al (1981), J.H.Allender et al (1983).

From the ODAP data available to the author (Fig. 3.a) the prediction model has been evaluated for the period in which there is a growing sea, so that we can expect quasi-homogeneous conditions. A rapidly growing wind dominates this period. The results are given in Fig. 3.b.

4. CONCLUSIONS

The response of wave directions, due only to the energy variation, under changing wind direction conditions can be summarized according to our results in three stages:

1^a) The high frequencies respond quasi-instantaneously, and quickly adjust to wind direction then remaining saturated in energy.

During this first stage the low frequencies do not react to the change in wind direction. This may be explained because its energy E_{Δ} , does not increased.

2^a) The low frequencies then begin to increase in energy, with a subsequent very rapid variation in its direction Ωb , that is very strong and has an inflexion point.

3^a) On approaching FDW for a given wind all the components tend asymptotically to the wind direction in the same way.

These three stages can be totally or partially completed, but are always in order and with the same characteristics. This behaviour is clear both in the measurements as well as in the numerical calculations for the ideal situations (Figs. 1 and 2).

It is worth mentioning that the theoretical directional model does fit well to the available data (Fig. 3).

As a consequence, it's logical to begin to use the directional results of the model in the engineering evaluations of wave forecasting and hindcasting.

The directional measurements currently available are very limited. An international data base is therefore proposed which would greatly assist future theoretical work.

CHAPTER 52

THREE DIMENSIONAL FLOW PROFILES ON LITTORAL BEACHES

Ib A. Svendsen, M.ASCE¹ and Rene S. Lorenz²

ABSTRACT: The problem of combined cross-shore and longshore currents generated by waves in and around a surf zone is considered in its full three-dimensional formulation. The equations for the two current components are decoupled and it is found that for a cylindrical coast with no longshore variations the longshore current variation with depth and distance from the shoreline satisfies a Poisson equation. This equation is solved by a perturbation method and it is shown that the longshore velocities are always larger than the velocities found by classical theory. In the simple uncoupled case, the full 3-D current profile is constructed by combining the results with cross-shore velocities determined in previous publications. Also, the total velocities are larger than velocities found from simple depth averaged models.

1. INTRODUCTION

The present paper deals with the variation over depth of the magnitude and direction of the wave induced mean currents on a beach.

In the past, the dept variation of wave induced currents have been studied for the purely two-dimensional case of cross-shore flow with particular aim at the seaward going undertow (among the latest contributions may be mentioned Stive & Wind (1986) and Svendsen & Hansen (1988)).

Longshore currents have mostly been analyzed in the simplified case of a long beach with straight bottom contours and no flow variations in the longshore direction. The first contributions date back nearly 20 years (Bowen, 1969; Thornton, 1970; Longuet-Higgins, 1970), and numerous works have been published on the topic since then. They all, however, consider depth integrated equations only, and therefore can only determine a sort of depth averaged value of the longshore current velocity.

Some contributions have claimed three dimensionality for the current description without actually being so. There is also a quasi-3D model inspired by river hydraulics was recently suggested by deVriend & Stive (1987) (essentially the same as Stive & deVriend, 1987). They divide the current motion into a primary part which has the direction and depth averaged magnitude of the net discharge; and a secondary flow which has zero depth mean, goes in the direction of the wave energy flux, and is generated by the wave motion. Further, the secondary current is assumed small relative to the primary current. As an example, however, the undertow is generated by the waves and has

¹Prof., Dept. of Civil Engrg., Univ. of Delaware, Newark, DE 19716 USA (Mail address for this paper).

²Research Engineer, Lic Engineering, Vimmelskafdet 47, 4, 1161 Copenhagen K, Denmark.

zero depth mean and hence would be a secondary current according to their definition. On the other hand, it will usually be significant in comparison to net flux current and for obliquely incident waves it will not be in the direction of the wave energy flux. Another example, the longshore current does not seem to fit into the idea that the secondary currents generated by the waves have zero depth mean. Thus the assumptions of de Vriend and Stive (1987) do not seem to cover those two important examples of wave generated currents.

In the present paper we shall take a very much different approach to the problem of three dimensional nearshore circulation and particularly discuss two aspects. One is the variation over depth of the longshore (as well as the cross-shore) currents. The other is the variation of the combined cross-shore and longshore flow. The discussion will be centered around the basic assumptions and the physical aspects of the solution. Readers are referred to Svendsen and Lorenz (1988) for some of the detailed derivations omitted here.

The starting point is taken from the three dimensional Reynolds' equations derived in the above mentioned reference for a combination of waves and wave induced currents in an environment with turbulence produced by primarily wave breaking. Although those equations are fairly general we concentrate the discussion here on the situation of a long straight coastline since some of the essential features of the combination of cross and longshore currents also appear in that canonical situation.

2. THE BASIC ASSUMPTIONS AND THE EQUATIONS USED

The flow situation on a beach corresponds to a combination of a turbulent, oscillatory (wave) motion and a current. In particular inside the breaker point the turbulence generated by the wave breaking will be very intensive.

The equations governing the wave induced currents can be derived from the general Navier-Stokes equations by transformations that correspond to turbulent (or ensemble) averaging (leading to Reynolds type equations) and to averaging over a wave period (corresponding to the equations derived by Whitham (1962) and Longuet-Higgins and Steward (1960,61)).

In accordance with the above description, the total velocity $\vec{u} = (u, v, w)$ is divided into three components by the relations

$$\left. \begin{aligned} u &= U + u_w + u' \\ v &= V + v_w + v' \\ w &= w_w + w' \end{aligned} \right\} \quad (2.1)$$

Here index w indicates oscillatory (wave) components, ' turbulent quantities. We use $\bar{\quad}$ to indicate ensemble averaging, which means that $\bar{u}' = \bar{v}' = \bar{w}' = 0$. Similarly, $\overline{\quad}$ denotes averaging over a wave period so that $\overline{u_w} = \overline{v_w} = \overline{w_w} = 0$ below trough level.

By the above mentioned averaging processes and eliminating the pressure by integrating the vertical component of the momentum flux we arrive at the following two equations for U and V, the horizontal current components.

$$\begin{aligned} \frac{\partial U}{\partial t} + \frac{\partial U^2}{\partial x} + \frac{\partial UV}{\partial y} + \frac{\partial (\overline{u_w^2} - \overline{w_w^2})}{\partial x} + \frac{\partial \overline{u_w v_w}}{\partial y} + \frac{\partial \overline{u_w w_w}}{\partial z} \\ = - \frac{\partial b}{\partial x} - \frac{\partial (\overline{u'^2} - \overline{w'^2})}{\partial x} - \frac{\partial \overline{u' v'}}{\partial y} - \frac{\partial \overline{u' w'}}{\partial z} \end{aligned} \quad (2.2)$$

and

$$\frac{\partial V}{\partial t} + \frac{\partial V^2}{\partial y} + \frac{\partial UV}{\partial x} + \frac{\partial(\overline{v_w^2} - \overline{w_w^2})}{\partial y} + \frac{\partial \overline{u_w v_w}}{\partial x} + \frac{\partial \overline{v_w w_w}}{\partial z} \\ - - g \frac{\partial b}{\partial y} - \frac{\overline{\partial v'^2 - w'^2}}{\partial y} - \frac{\overline{\partial u' v'}}{\partial x} - \frac{\overline{\partial v' w'}}{\partial z} \quad (2.3)$$

Eqs. (2.2) and (2.3) are in principle the momentum equations governing the wave induced current motion and it is those equations that are examined further in the following. They differ from the usual depth averaged equations in that they are not integrated in the vertical direction. Thus U, V are in general functions of x, y and z. The equations are only valid below trough level.

In order to solve these equations for U, V it is necessary

- to assume that the terms with index w representing the wave motion are determined by some wave theory or by measurements.
- to model in terms of quantities determined otherwise the turbulent normal and tangential stresses.

In the present context, we do not loose any of the effects we want to examine by using a simple time-independent eddy viscosity model for the turbulence. Besides, this has been shown for the cross shore flow to yield very reliable results (see e.g. the earlier quoted references and Svendsen et al. (1987)). Hence we let

$$\left. \begin{aligned} \overline{u' v'} \quad , \quad \overline{v' w'} &= -\nu_t \left[\frac{\partial V}{\partial x} \quad , \quad \frac{\partial V}{\partial z} \right] \\ \overline{u' w'} &= -\nu_t \frac{\partial U}{\partial z} \end{aligned} \right\} \quad (2.4)$$

in which we have already introduced the simplification of uniform flow conditions in the longshore direction ($\partial/\partial y = 0$). We also neglect the turbulent normal stresses.

3. THE FLOW PROFILES ON A CYLINDRICAL COAST WITH NO LONGSHORE VARIATIONS

This canonical case corresponds to letting $\partial/\partial y = 0$ in both (2.2) and (2.3) which yields equations amenable to analytical solution without the essential features of the flow are lost. We also limit our considerations to time independent current patterns. Hence the equations we consider for further simplification are the following

$$\frac{\partial}{\partial x} \left[U^2 + gb + (\overline{u_w^2} - \overline{w_w^2}) \right] + \frac{\partial \overline{u_w w_w}}{\partial z} = - \frac{\partial(\overline{u'^2 - w'^2})}{\partial x} + \frac{\partial}{\partial z} \left[\nu_t \frac{\partial U}{\partial z} \right] \quad (3.1)$$

and

$$\frac{\partial}{\partial x} \left[UV + \overline{u_w v_w} \right] + \frac{\partial \overline{v_w w_w}}{\partial z} = \frac{\partial}{\partial x} \left[\nu_t \frac{\partial V}{\partial x} \right] + \frac{\partial}{\partial z} \left[\nu_t \frac{\partial V}{\partial z} \right] \quad (3.2)$$

where also (2.4) has been substituted.

The Cross-Shore Motion

With suitable additional simplification (3.1) becomes the equation solved in the literature for undertow. Several of those simplifications were analyzed by Stive & Wind (1982) and Svendsen et al. (1987), using measurements to calculate the magnitude of the $\overline{w_w^2}$,

the $\overline{u'^2} - \overline{w'^2}$ and U^2 terms. Although the U^2 term is found not to be quite negligible, the measurements used by Svendsen et al. (1987) show that the dominating driving term in (3.1) is the $\partial b / \partial x$ - term. $\partial \overline{u_w^2} / \partial x$ is only 10-20% of that and the other terms are even smaller.

The measurements also show that $\overline{u_w^2}$ is remarkably constant over depth, a fact that has been further confirmed by later, yet unpublished, laboratory results.

The $\partial \overline{u_w w_w} / \partial z$ term has also been neglected in all previous investigations. It represents the net horizontal shear stress on a fluid particle generated by the oscillatory wave component. For constant depth wave theories (such as the linear wave theory which is often used for the wave contributions) this term is identically zero (except in the boundary layer). On a sloping bottom we have no wave theory from which we can evaluate the term. Simple estimates suggest, however, that the term is substantially smaller than $\partial \overline{u_w^2} / \partial x$. Hence in spite of the principal importance of the $\partial \overline{u_w w_w} / \partial z$ term in deriving the depth integrated version of the equations, it is a good approximation locally to disregard this term in the equation for cross-shore currents.

With the assumed constant eddy viscosity and with the driving term

$$\alpha_1 = \frac{\partial}{\partial x} \left[gb + \overline{u_w^2} - \overline{w_w^2} + U^2 \right] \quad (3.3)$$

uniform over depth the solution for the undertow may be written

$$U = \frac{1}{2} \frac{\alpha_1}{\nu_t} \zeta^2 + \frac{A_1}{\nu_t} \zeta + U_b \quad (3.4)$$

where A_1 is an integration parameter related to the mean bottom friction. U_b is the bottom value of the undertow profile if extended to the bottom without consideration of the bottom boundary layer. For a closer discussion of evaluation of A_1 and U_b reference is made to Svendsen & Hansen (1988).

The Longshore Motion

The longshore motion is given by (3.2). The additional simplification needed to make this equation solvable is related to the UV-term. This term represents the effect which the undertow has on the longshore current. Although this effect may locally be appreciable it can readily be shown that averaged over depth the contribution will be almost nil. In order to proceed we choose here to neglect the term. Then (3.2) reduces to

$$\frac{\partial}{\partial x} \left[\nu_t \frac{\partial V}{\partial x} \right] + \frac{\partial}{\partial z} \left[\nu_t \frac{\partial V}{\partial z} \right] = \frac{\partial \overline{u_w v_w}}{\partial x} + \frac{\partial \overline{v_w w_w}}{\partial z} \quad (3.5.)$$

Since the right hand side is considered known, this is a Poisson equation for the variation of the longshore current velocity V over depth and cross shore directions.

It may be noticed that the effect of neglecting the UV-term is that the equation for the longshore current becomes independent of the solution for the cross-shore current. Similarly, in the general case of arbitrary bottom topography this would have freed the cross shore current from dependence of the longshore current solution.

Eq. (3.5) may also be written

$$\nabla(\nu_t \nabla V) = g_{xy}$$

where

$$g_{xy} = \frac{\partial}{\partial x} \left(\overline{u_w v_w} \right) + \frac{\partial}{\partial z} \left(\overline{v_w w_w} \right)$$

4. SOLUTION FOR THE LONGSHORE CURRENT VARIATION WITH x AND z

It turns out that by physically realistic assumptions about magnitude of the terms in (3.5) and the boundary condition at the bottom (3.5) can be solved by a perturbation technique which as the first approximation has the classical solution for depth averaged longshore current velocity.

First we notice that since (3.5) is an elliptic equation it requires boundary conditions along the full boundary.

The forcing term $g(x,y)$ will only be non-zero shoreward of the transition point, x_t (Svendsen, 1984). Hence, at x_t , g_{xy} is discontinuous and matching of solutions must be arranged as in traditional longshore current solutions with depth independent velocities.

Eq. (3.5) is only valid below wave trough level. Therefore another boundary condition is that at the trough level

$$\tau_{zy} = \rho \nu_t \frac{\partial V}{\partial z} = \frac{\partial}{\partial x} S_{xy,s} \quad \text{at } x = \eta_t \quad (4.1)$$

where $S_{xy,s}$ is the radiation stress contribution above trough level, and η_t is the wave trough level. This boundary condition is introduced into the mathematical formulation by combining it with the requirement that (3.5) be satisfied at all z below trough level to yield the depth integrated momentum balance which becomes

$$\frac{\partial}{\partial x} \int_{-h_0}^b \rho \nu_t \frac{\partial V(x,z)}{\partial x} dz - \tau_{yb} = \frac{\partial S_{xy}}{\partial x} \quad (4.2)$$

For V independent of z this expression reduces to the well known

$$\frac{\partial}{\partial x} \left(\rho \nu_t h \frac{\partial V}{\partial x} \right) - \tau_{yb} = \frac{\partial S_{xy}}{\partial x} \quad (4.3)$$

which is the equation normally solved for longshore currents.

The most important boundary condition, however, is at the bottom. Here we have an oscillatory boundary layer in which the turbulent eddy viscosity can be assumed much smaller than above (Svendsen et al., 1987). In contrast to cross-shore flow, however, the bottom shear stress is the (exterior) force resisting the driving radiation stress gradient. In this context the horizontal turbulent mixing--represented by the $\partial/\partial x(\nu_t \partial V/\partial x)$ term--only redistribute the radiation stress contributions from one place to another, and the

integral of all radiation stresses from sea to shore must equal S_{xy} at the breaker point.

The boundary layer at the bottom will yield a relationship between the bottom velocity V_b and the bottom shear stress $\tau_{y,b}$, and we assume that this relationship can be represented by a generalization of the expression derived by Svendsen & Hansen (1988)

$$\tau_{y,b} = \left(\rho \nu_t \frac{\partial V}{\partial z} \right) = \frac{1}{2} \rho f_w u_{wb} V_b \quad (4.4)$$

where f_w is the friction factor for waves only, u_{wb} the oscillatory particle velocity in the wave direction. It is emphasized that although this expression formally may resemble the frequently used relationships between bottom shear stress and depth mean velocity (4.4) is actually based on the elaborate wave current boundary layer theory by Christoffersen & Jonsson (1983).

The turbulent mixing term cannot be neglected even in a first approximation since that would change the degree of the differential operator in the x-direction and radically change the nature of the x variation of V (Longuet-Higgins, 1970).

With the turbulence mixing as a modifying term, however, the longshore flow is very much a balance between the driving radiation stress gradient and the resisting τ_{zy} shear stress. Thus, if we for a moment assumed the right hand side of (3.5) and the turbulent mixing were uniformly distributed over depth then τ_{zy} would vary linearly over depth, with the largest values at the bottom. The small viscosity inside the bottom boundary layer and much larger value above therefore means that by far the largest velocity gradients will occur within the bottom boundary layer. Or, in other words, the velocity outside the boundary layer will only show a moderate variation in comparison to the variation inside the boundary layer.

Mathematically this can be expressed by assuming that the first approximation to the longshore current velocity is independent of z . Thus we assume a perturbation expansion of the form

$$\left. \begin{aligned} V &= V_0(x) + \epsilon V_1(x, z) + \dots \\ \tau_{yb} &= \tau_0(x) + \epsilon \tau_1(x) + \dots \\ V_b &= V_{b0} + \epsilon V_{b1} + \dots \end{aligned} \right\} \quad (4.5)$$

In order to obtain a consistent modification of the equations (3.5), (4.2) and (4.4) a scaling is required which introduces the assumption that the width of the surf zone $x_s - x_t$ is $\ll h_t$ where h_t is the depth at the transition point x_t . It is also utilized that

$$\frac{f_w}{\nu_t} h_t \sqrt{gh_t} = O(s_x^2) \quad (4.6)$$

where $s_x = \epsilon^{1/2}$ is a characteristic value of the bottom slope. With

$$X = -s_x x \quad ; \quad Z = z \quad ; \quad \epsilon = s_x^2 \ll 1$$

the modified equations become

$$\epsilon \frac{\partial}{\partial X} \left[\nu_t \frac{\partial V}{\partial X} \right] + \frac{\partial}{\partial Z} \left[\nu_t \frac{\partial V}{\partial Z} \right] = -\epsilon g_{xy} / s_x^2 \quad (3.5a)$$

$$\frac{\tau_0}{\rho\nu_t} = \left(\frac{\partial V}{\partial z} \right)_{-h_0} = \epsilon \frac{1}{2} \frac{f_w}{\nu_t s_x^2} u_{wb} V_b \quad (4.4a)$$

and

$$\epsilon \frac{\partial}{\partial X} \int_{-h_0}^b \rho\nu_t \frac{\partial V}{\partial X} dz - \tau_{yb} = \frac{\epsilon}{s_x^2} \frac{\partial S_{xy}}{\partial x} \quad (4.2a)$$

The first order approximation shows that since $V_0 = V_0(x)$ outside the boundary layer we get $\tau_0 = 0$.

The system also yields $V_{b0} = V_0$ and hence

$$\frac{\tau_1}{\rho\nu_t} = \frac{1}{2} \frac{f_w}{\nu_t s_x^2} u_{wb} V_0 = \left(\frac{\partial V_1}{\partial z} \right)_{-h_0} \quad (4.7)$$

V_0 is then determined from (4.2), and since V_0 is independent of z (4.2) takes the form of (4.3)

$$\frac{\partial}{\partial X} \left(\rho\nu_t h \frac{\partial V_{b0}}{\partial X} \right) - \tau_1 = \frac{1}{s_x^2} \frac{\partial S_{xy}}{\partial x} \quad (4.8)$$

where τ_1 is given by (4.7).

Thus we have found that the first approximation V_0 to the longshore velocity V is determined exactly by the equation which has so far been used in the literature for depth averaged longshore current velocities. V_{b0} , however, is not the depth averaged value of V as we shall see shortly.

Carrying the computations through to second order we find that

$$\begin{aligned} V(x,z) &= V_0 + \epsilon V_1 \\ &= V_{b0} + \epsilon V_{b1} + \frac{1}{2} \left(g_{xy} - \frac{\partial}{\partial x} \left(\nu_t \frac{\partial V_0}{\partial x} \right) \right) (z+h_0)^2 \\ &\quad + \frac{f_w}{2\nu_t} u_{wb} V_{b0}(z+h_0) \end{aligned} \quad (4.9)$$

Here V_{b1} can be determined from the differential equation

$$\frac{\partial}{\partial X} \left(\nu_t h \frac{\partial V_{b1}}{\partial X} \right) - \frac{1}{2} \rho f_w u_{wb} V_{b1} = -F(x) \quad (4.10)$$

where $F(x)$ is a known function of x determined from the first order solution. One important observation here is that (4.9) shows that the depth average of V is always larger than V_{b0} , $V_{b0} = V_0$ is in fact the smallest velocity in the profile.

The results also show that there is a correction V_{b1} to the bottom velocity V_{b0} found by the traditional longshore current equation (4.8). This correction is entirely due to the fact that in (4.8) we

use V_0 to evaluate the turbulent mixing, not V . Since V_{b1} will normally be a small term, we may get a good approximation to V by neglecting V_{b1} . That yields

$$V(x, z) \approx V_{b0} + \frac{1}{2} \frac{g'_{xy}}{\nu_t} (z+h_0)^2 + \frac{f_w}{2\nu_t} u_{wb} V_{b0}(z+h_0) \quad (4.11)$$

where

$$g'_{xy} = g_{xy} - \frac{\partial}{\partial x} \left[\nu_t \frac{\partial V_{b0}}{\partial x} \right] \quad (4.12)$$

5. NUMERICAL RESULTS FOR THE LOCAL LONGSHORE CURRENT VELOCITY PROFILE

For both V_0 and V_1 , a full solution for the local profile requires that we solve the differential equations (4.8) and (4.10) for V_{b0} and V_{b1} , respectively. Properly done this also implies determination of the wave height variation across the surf zone to establish the variation of S_{xy} .

To illustrate the nature of the results, however, let us neglect the effect of the turbulent mixing and concentrate on the local velocity profiles only. This implies that $g'_{xy} = g_{xy}$ in (4.11).

Using Svendsen's (1984) description of the surf zone waves with a shape factor $B_0 = \eta^2/H^2$ to account for the breakers we get

$$\overline{u_w w_w} = g \left(\frac{H}{h} \right)^2 h B_0 \frac{c^2}{gh} \sin \alpha \cos \alpha$$

where α is the angle of incidence for the waves. Approximating the $\partial \overline{v_w w_w} / \partial z$ term in a way that satisfies the known requirements for that term (for details see Svendsen & Lorenz, 1988) then yields

$$g_{xy} = \frac{5}{2} \left(\frac{H}{h} \right)^2 B_0 \frac{c^2}{gh} \frac{\partial h}{\partial x} \sin \alpha \cos \alpha$$

and

$$\frac{\partial S_{xy}}{\partial x} = \rho gh \frac{\partial h}{\partial x} \left(\frac{H}{h} \right)^2 \left[\frac{5}{2} B_0 + 3 \frac{A}{H^2} \frac{h}{L} \right] \sin \alpha \cos \alpha$$

where the second term originates from the shear stress created at wave trough level by the surface roller. A is the roller area and L the wave length.

Fig. 1 shows some examples of velocity profiles obtained by using the following values of the parameters.

Phase velocity	$c = \sqrt{gh}$
Bottom friction coefficient	$f_w = 2 \cdot 10^{-2}$
Breaker shape	$B_0 = \eta^2/H^2 = 0.08$
Roller contribution	$\frac{Ah}{H^2 L} = 0.09$
Eddy viscosity	$\nu_t/h\sqrt{gh} = 0.015$

Beach at $x = 0$ m

Breaking point at $x = 2.51$ m

Fig. 3. Measurements of longshore velocities at three different elevations above the bed (from Visser, 1984).

The absence of turbulent mixing makes the calculated velocities larger than real. The important conclusion, however, is that the velocity profiles are very different from the logarithmic profile sometimes assumed in analogy with open channel flow. Fig. 2 shows a comparison between the two profiles. In fact the assumption of a uniform velocity over depth would be much closer to the real velocities than would a logarithmic profile. It also implies that the near-bottom velocities are significantly larger than for a logarithmic profile.

It may be emphasized that since the classical longshore current velocity found e.g. by Louguet-Higgins corresponds to $V = V_{b0}$, the real velocities will always be 10-20% larger than those found by classical theory.

Fig. 3 shows measurements of longshore currents in the surf zone at three different elevations above the bottom (from Visser, 1984). We see that the nature of the variation of depth is qualitatively in agreement with the theoretical profiles shown in Fig. 1.

6. COMBINED LONGSHORE AND CROSS-SHORE VELOCITY PROFILE

In the simplified case described here of no coupling between the cross-shore and the longshore current (the UV term in (3.2)) the total 3D velocity profile can be constructed by a simple vector addition of the cross-shore and the longshore velocity profiles determined independently. Such a 3D profile is shown in Fig. 4.

FIG. 4. The full 3-D current velocity profile as it occurs in a situation with both an undertow and a longshore current.

The result shows features that are of significant importance for the sediment transport on a coast.

From the knowledge of the fact that a strong undertow will be present in a surf zone even with no net cross shore current, we know that there is a tendency that sediments are being carried seaward by the current. The 3D profile, however, shows that close to the bottom the current direction may actually deviate 45° or more from the depth mean current vector which in this case is purely along-shore.

Moreover, if e.g. the longshore and crossshore bottom current velocities are of equal magnitude the total current velocity is 40% larger than given by a depth averaged model. Hence it can be quite misleading to use depth averaged models to predict bottom currents in the surf zone.

The predictions of the described 3D velocity profile are qualitatively confirmed by the tracer sediment observations by Ingle (1966). Fig. 5 shows a summary of his results.

FIG. 5. Sediment movements in and near the surf zone. Summary of tracer observations by Ingle (1966).

CHAPTER 53

GRAIN-GRAIN INTERACTION IN OSCILLATING SHEETFLOW

W.T. Bakker¹⁾, W.G.M. van Kesteren²⁾ and Z.H. Yu³⁾

ABSTRACT

Viscous grain-grain interaction is an important aspect of the dynamics of oscillating sheetflow. This interaction between sand grains has been investigated qualitatively in a pulsating water tunnel. Furthermore, experiments concerning the interaction between neutrally buoyant spheres in a Couette flow have been carried out at a scale of 100:1 in a new developed ring shear apparatus, called "Carrousel."

With respect to the dynamics of sheetflow, in-situ measuring devices for the sand concentration in the sheetflow ("Harp") and the bed load ("Swan") has been developed; some preliminary results are shown.

For sand grains, the intrusion depth of sheetflow appears to be of the order of several mm. On high speed video recordings no lateral mixing between grain layers can be observed; for this some physical explanation is given. This supports the modelling of the sheetflow mechanism as moving grain layers.

1. INTRODUCTION.

For a good understanding of coastal behaviour and for accurate coastal field models, knowledge about sheetflow is indispensable.

From theoretical investigations (for instance Lofquist (1978), Mogridge (1972), Nielsen (1979) and Van Kesteren (1982)) and from visual observations from Dingle and Inman (1976) the impression arises that for normal beach sands ($D_{50} \approx 200 \mu\text{m}$) sheetflow occurs, when orbital velocities surpass an order of magnitude of 1 m/s. Fig. 1 shows visual observations of Yu (1987) made along the Dutch coast.

The impression exists, that generally sheetflow occurs at the seaward side of breaker bars and in the uprush zone.

This paper contains more a progress report on sheetflow studies than clear-cut solutions. It has to be seen in the context with former papers on the same subject (Bakker and Van Kesteren (1986) and (1987)) and with papers on near-bottom velocities (Bakker and Van Doorn (1978) and Van

²⁾ Project Engineer Delft Hydraulics.

³⁾ Researcher Forschungsstelle Küste Norderney.

Kesteren and Bakker (1984)), which finally are due to merge into an integrated model for the sediment transport under sheetflow conditions. The recent research is concentrated on two subjects, which are considered the main bottle-necks with respect to the solution of the sheetflow problem: the transmission of the shear stress from the turbulent boundary water layer to the sheetflow (treated in a preliminary way in Bakker and Van Kesteren (1987)) and grain-grain interaction, which is the subject of the present paper. First the preliminary results of new laboratory experiments in the Large Pulsating Water Tunnel of Delft Hydraulics (ch. 2.1) and in the Carrousel of Delft University of Technology (ch. 2.2) are presented, as well as the results of some measurements in nature (ch. 2.3). Furthermore, some theoretical considerations with respect to the importance of lift forces on grains in a high concentrated granular shear flow are given (ch. 3). Chapter 4 gives the conclusions.

2. EXPERIMENTS.

2.1. PULSATING WATER TUNNEL.

In order to observe the sheetflow mechanism into detail some tests on sand with a mean diameter of $220 \mu\text{m}$ were performed in the Large Pulsating Watertunnel of Delft Hydraulics. The occurrence of sheetflow was observed in a harmonically oscillating flow with a period of 6 s and a maximum velocity of 1.6 m/s.

The behaviour of the sand near and in the bed was recorded with high-speed video (200 and 400 frames/s) (see photo 1). The camera was focussed on an area of $5 \times 7 \text{ mm}$ and $10 \times 14 \text{ mm}$ respectively. Although the velocities within this area exceeded 1 m/s the position of the top and bottom of the sheetflow layer remained constant within a range of only a few grain diameters.

Fig. 2 shows an example of particle velocities within an area of $10 \times 14 \text{ mm}$; the velocities are obtained from two sequential frames (time interval 5 ms) using the frame-freezing and overlay technique of the high-speed video equipment. Fig. 3 shows velocity distributions measured in this way at 6 equal time intervals of $1/10$ of the wave period.

When the velocity distributions are compared with the velocity just outside the turbulent boundary layer (arrows in top of fig. 3) a very significant phase lag of more than 45 dgr. can be observed. This is consonant with the phaselag between shear stresses and velocities in the turbulent boundary layer (see Bakker and Van Kesteren (1986) and Horikawa et al. (1982)).

In fig. 4 the intrusion depth (i.e. the depth of the point of zero velocity) during half a wave period is shown. The maximum depth occurred before the time of maximum velocity outside the turbulent boundary layer ($t = .2T$). A phase lag of the same order was found by Horikawa et al. (1982).

The observations revealed the following important features of the sheetflow mechanism:

- * No lateral mixing can be observed, even at high shear-rates (500 s^{-1}); this supports the modelling the sheetflow mechanism as moving grainlayers.
- * As the name of the flow already indicates, the subsequent erosion of grain layers occurs in the way of the mobilisation of sheets of the paperfile in a foto-copier.

- * The deposition of moving grains at the time of current reversal occurred uniformly in horizontal direction in a very short time (10 - 20 ms); because of the high concentration settlement can occur without much vertical motion.
- * All over the wave period but especially at the time of current reversal a density wave within the sheetflow layer can be observed. These waves might indicate that, in accordance with Bakker and Van Kesteren (1986), the transfer and dissipation of the turbulent shear stress in the sheetflow layer takes place by the means of viscous waves generated by the turbulent pressure wave caused by burst-phenomena in the boundary layer acting on the top of the sheetflow-layer.

2.2. CARROUSEL.

At the Delft University of Technology the grain - grain interaction is investigated by using a grain ring shear apparatus called Carrousel. Fig. 5 shows a plan view; photo 2 shows the set-up.

In the annular space between two concentric cylindrical walls ($\phi = 1062$ mm. resp. $\phi = 1198$ mm.) and a bottom and a top ring, a mixture of polypropene spheres ($\phi=14$ mm, $\rho=870$ kg/m³), immersed in oil with the same density is contained. The viscosity of the oil is 10^{-4} m²/s at 18°C. The top ring can be adjusted with respect to its height. Four rings of half spheres are glued on both rings in a regular pattern (vide photo 3)

This mixture is sheared by rotating the top ring with velocities up to 4 m/s while the bottom ring is fixed.

Fig. 5b shows the way of measuring the forces on the bottom ring with 3 "gallow"-shaped metal bearings, provided with strain gauges.

Thus grain-grain interaction can be investigated at a scale 100:1.

The apparatus is in the stage of calibration; some first results are shown in photo 4a,b,c, which will be discussed in ch.3 .

2.3. MEASUREMENTS IN NATURE.

In cooperation with the Forschungsstelle Küste at Norderney (Dr.H.Niemeyer) a measurement project "Lohengrin" has started, involving the development of two measuring instruments, a "Harp" and a "Swan". The Swan (vide photo 5) is dug into the sand (fig. 6) only its tail and neck rise above.

It feeds itself through its tail; the sediment comes to rest in its body and the water is discharged through its beak; the amount of it is measured with a flow meter (e).

When the current reverses, a repercussion valve (f) in the beak hinders an internal flow reversal.

Distance between tail and beak is so designed, that the own frequency of the water in the instrument allows an equal velocity in the entrance as in the sheetflow layer. The height of the opening in the tail can be adjusted; normally it is 12 mm. Also the height of the tail itself can be adjusted by a diver; it is essential, that it remains on the same level as the sand bottom.

Up to now, average concentrations over a height of 12 mm of 4 to 34 gr/l were measured (Yu (1987)). However, still more calibration should be done.

A very simple prototype of this instrument has been developed in 1983 by the first author and prof. dr.H.Krock of the Look Laboratory in Hawaii; since then it has been tested and developed by the third author along

Dutch beaches and in the laboratory for Fluid Mechanics of Delft University of Technology (Yu (1987)) and, at present, in Norderney.

A second instrument in developing stage, to be tested at the Forschungsstelle Küste, is the Harp.

It consists of 3 concentration probes, sensing at a different level in the sheetflow (fig. 7). The probes are mounted in upward direction on a lower bar under the sand, which is connected to a frame, consisting of 2 poles driven into the beach sand and an upperbar between. The whole lower bar can be lifted, as it is connected with screws to the upper bar of the frame.

The concentration probes consist each of 4 electrodes of 1 mm. protruding from a probe head of 10 x 2 mm (fig. 8). A 2 kHz AC is generated between the outer electrodes and the voltage difference (electrical resistance) between the inner electrodes is measured.

Fig. 9 gives the calibration curve between the relative resistance and the volumetric concentration (from Mastbergen and Bezuijen (1988)).

Fig.10a,b shows the situation in Norderney where the instruments are tested, in the swash zone between the groyne fields D and E.

Up to present, no three-level measurements are available; fig.11 and 12 show measurements resulting from 1 sensor.

In fig.11 showing concentration versus time, one probe is driven into the bottom, thus giving a concentration of about 50%, but still reacting on the waves. At arrow "A" the probe is lifted over 2 mm. The lifting causes a hole (lower concentration) which fills up quickly again. After some waves the whole bottom lowers obviously, thus causing a low concentration at the instrument. Now wave motion causes an increase in concentration.

After ca. 15 seconds the old situation is restored, more or less and later on again the concentration decreases. Lifting the probe again 2 mm (arrow B) leads to analogous results, however now with a lower mean concentration. The next lifting of the probe (arrow C) brings it out of the sheetflow area. Now only accidentally high concentrations occur.

The local range of the sheetflow layer (from maximum concentration up to suspended load concentrations) thus shows to be of the order of 6 mm.

Fig.12 shows an interrelation between sheetflow concentration and orbital velocities measured ca. 20 cm. above the bottom. Here the probe is kept stationary at a rather high level.

There is shown respectively: the concentration, the cross-shore and longshore component of an electromagnetic current meter and the wave height, measured with a pressure meter. Averaged concentrations of about 3% are found.

3. THEORETICAL ASPECTS.

Little grains love physical law and order. This is confirmed by observations during preliminary tests in the grain Carrousel (photo 4a,b,c). When the distance between the upper and bottom ring is decreased, the neutrally buoyant spheres do not only center themselves between the rings, but also show a preference for equally mutual distance and for the same orbit, situated halfway the outer ring of spheres glued on the steel rings and the adjacent ring of spheres.

Sometimes a rebel grain, deviating too much from neutral buoyancy, disturbs the order causing some rattling in the Carrousel, but mostly the order is restored quickly.

The number of 'free' grains in the tests was half the number of glued grains on one ring.

Experimentally and theoretically, the centering force has been investigated by quite a school of investigators, from which will be mentioned : Halow and Wills (1970), Vasseur and Cox (1976) and Ho and Leal (1974).

The last two papers deal with theory concerning a neutrally buoyant sphere in a Couette flow between two (flat) plates. The first one gives as well theory as experimental results concerning radial migration of a sphere in the annular region between two concentric cylinders, of which the outer one was in rest and the inner one was rotating. The theoretical considerations of the last two papers seem more adequate than the ones of Halow and Wills (1970), as a confined space is considered, where Halow and Wills use Saffman's theory (1965), valid for Couette flow in an unconfined space.

From Vasseur and Cox (1976) a velocity \dot{x} of a neutrally buoyant sphere in the vicinity of the central position can be derived, equal to:

$$\dot{x} = - \frac{x r^3 S^2}{3.5 h \nu} \quad (1)$$

where x is the deviation from the central position, h is the distance between the plates, r is the radius of the sphere, S is the vertical velocity gradient and ν is the kinematic viscosity of the fluid.

Reading (1) as a differential equation (neglecting the inertia of the grain itself), one finds for the 'neperian' time T_e , in which the distance to the central position reduces with a factor e :

$$T_e = 3.5 \frac{h \nu}{r^3 S^2} \quad (2)$$

Neperian times T_e of 4 and 9500 s, found in this way for two experiments of Halow and Wills (1970), (their fig. 4 and 5) are not inconsistent with their results. For the Carrousel experiments neperian times of 0.3 s or less are found.

For natural grains (for instance a velocity gradient $S = \Delta u / \Delta z = 100 \text{ s}^{-1}$ (velocity difference Δu of 0.5 m/s over a layer thickness Δz of 0.05 m); $r = 10^{-4}$ m, $h/r = 4$, $\nu = 10^{-6} \text{ m}^2/\text{s}$ one finds $T_e = 0.14 \text{ s}$).

Deriving the maximum lift velocity from Vasseur and Cox (1976) and using (1) one finds the order of magnitude of 1 mm/s, i.e. small with respect to the unhindered settling velocity of grains, but essential when using mechanism, exposed in by Bakker and Van Kesteren (1986).

However, the self-centering capacity of grains did not show to be so dominant, that a total layer of grains in the Carrousel pops into position (i.e. in an experiment similar to that shown in photo 6, but with a higher concentration of grains).

The reason for this (too much density differences?) is subject of future research.

4. CONCLUSIONS.

As well in the field as in the laboratory (Pulsating Water Tunnel) the result of Horikawa et al. (1982), that the intrusion depth of sheetflow is of the order of several mm has been confirmed.

High Speed Video recording reveals that layers of grains shear with respect to each other, without lateral mixing. Theoretically, shearing grain layers in a viscous medium should show the tendency to centering themselves with respect to adjacent layers. This effect is also observed

in tests with neutrally-buoyant grains sheared in a ring shear apparatus (Carrousel). This self centering effect can be explained by lift forces caused by inertia of the fluid surrounding the grains.

ACKNOWLEDGMENTS.

The authors acknowledge the support from the Forschungsstelle Küste, Norderney (Dr. G. Luck, Dr. H. Künz and Dr. H. Niemeier) and their consent of publishing about the measurements at Norderney.

The Carrousel would never have delivered results without the designing of ir. H. Havinga, the construction by mr. Groeneveld and the experiments carried out by mr. W. Klomp (all Delft University of Technology).

Hi-Speed video was made possible by courtesy of mr. Reinders of Reinka B.V.

CHAPTER 54

Nonlinear effects on focussed water waves

by

D.H.Peregrine*, D.Skyner[†], M.Stiassnie[‡] & N.Dodd**

Abstract

A brief account is given of theory and experiments for water wave focussing. The theory uses weakly nonlinear wave modulation theory, that is the nonlinear Schrödinger equation, summarises earlier theoretical papers and augments them with numerical results. Experiments were performed to compare with theory. The limited comparison shown here indicates that the theory gives satisfactory results even for waves close to breaking. Both the numerical and experimental results indicate the importance of linear diffraction when waves are focussed. The relevance of diffraction is easily assessed, and is likely to dominate in many coastal examples of weak focussing.

Introduction

In practical examples of water-wave refraction, ray diagrams frequently show rays crossing. Often the initial ray intersections involve only a few rays with no well defined structure apparent. Any crossing of rays is an indication that the ray-theory approximations have become invalid, and a greater density of rays will normally reveal a focussing of rays near the initial crossing point. In practice simple smoothing or averaging methods are sometimes used to calculate wave heights. Where these have no rational basis there is always an uncertainty about possible steep waves due to focussing being missed.

Diffraction effects need to be included in order to obtain accurate solutions near a focus. In addition, if waves are steep nonlinear effects are significant. This paper reports on theoretical and experimental work.

Model examples

In order to clarify ideas we consider two simple cases. In each case we suppose that waves have already suffered refraction due to propagation over a shoaling area or through non uniform currents which focus them but that the waves now propagate toward a focus over water of uniform depth. The focussing portion of the wave front is taken to be circular subtending an angle $2a$ at the focus which is at a distance f . The rest of the wave front is taken to be straight. In case (a) waves away from the focussing region are taken to be parallel to the central ray through the focus, and in case (b) they are taken to be smooth straight extensions of the circular arc; see figure 1.

In case (a) there are no further ray crossings until well beyond the focus and study can be directed to wave amplitudes in the focal region. In case (b) waves from both sides continue to cross behind the focus and wave amplitudes can be expected to be at least twice those of the original wave train, and any exception near the focus is of interest.

Figure 1 Two examples of wave focussing (a) where the focussing region is not influenced by the wave front on each side of the initial focussing wave. (b) where the waves each side of the focussing wave meet close to the focussing region.

Linear waves

Since solutions of the linear wave equation may be superposed, the initial conditions may be broken down into sub-problems: two semi-infinite plane waves with their attendant diffraction and the focussing arc. The latter is of the greater interest since the half-plane waves correspond to Sommerfeld's solution for diffraction by a semi-infinite barrier. Exact solutions of the linear problem are easily created by adding plane-wave solutions. We have used one particular example to represent a focussing arc. It is a set of N plane waves of equal amplitude and equal angular spacing in the range $(-\alpha, \alpha)$ all in phase at the focus. We call this example F and it is taken to be illustrative of the case shown in figure 1(a).

It is easy to compute solutions for example F corresponding to the focus having differing angles 2α of incoming waves and different distances, f , from an initial line. The effects of diffraction show for $\alpha = 15^\circ$ and a focal distance $f = 10L$, (L is wavelength), this exact solution shows an increase of amplitude over the initial conditions of only 20%. This small increase is due to diffraction counter balancing the focussing effects. On the other hand initial conditions with the same value of α but larger values of f do lead to focussing with enhancement of wave amplitude, so that it might approach the estimate of $2\alpha(2f/L)^{\frac{1}{2}}$ given, in different notation, by Peregrine (1986).

The effects of diffraction scale with the Fresnel number

$$N = a^2 f / L.$$

The example given above, with $N = 0.7$, is chosen since it represents a balance between diffraction and focussing. For large N , focussing is dominant. In any specific example it is easy to calculate N and assess diffraction. For example, if waves have a wavelength of 80 metres and part of the wave front of angle 20° , i.e. $\alpha = 10^\circ = 0.174$ radius, focusses at a distance of 2000 metres, then $N = 0.76$, which implies strong diffractive effects

Nonlinear waves

A major effect of nonlinearity on refraction is wave defocussing. Some aspects of this are described in Peregrine (1983, 1985 and 1986) for examples where Stokes's wave theory is a good approximation for periodic waves, i.e. not too shallow water. From a practical point of view this defocussing is reassuring since the nonlinear effects are reducing maximum amplitudes. However, unlike linear waves, theory shows that the effects of the waves bounding the waves that focus cannot be treated by simple superposition of solutions.

For the configuration of figure 1(a) the bounding waves do not contribute significantly more energy to the focussing region, in fact they act to spread the disturbance of the wave front more rapidly, since nonlinear effects lead to a "splitting" of linear rays (Peregrine, 1983).

More care is needed when assessing the effects of converging waves such as in figure 1(b). Here linear theory indicates that behind the focussing region the bounding waves contribute twice the initial amplitude as they are superposed. On the other hand for small angles, 2α , between these waves the nonlinear theory indicates formation of a 'wave jump'. Such jumps were identified by Yue and Mei (1980) and

further studied by Peregrine (1983). They give rise to a "Mach stem" type of interaction between the two wave fields. The height of the Mach-stem may be greater or less than twice the height of the incident waves as may be seen from careful study of figures 3 and 4 in Peregrine (1983). One figure is for deep water waves, the other for solitary waves ("Wedge angle" on these figures should be identified with α here).

In the above-mentioned figures amplifications as high as four times the incident waves appear possible. Such amplifications have not been observed in experiments and there are indications that diffraction effects may limit all or most of these excessive amplifications especially in deeper water. For solitary waves the maximum amplification observed by Melville (1980) in experiments on Mach stem reflection was no greater than twice, but Funakoshi's (1980, 1981) computations with the Boussinesq equations do include an example with an amplification of nearly three times.

Numerical solutions

The linear superposition of waves described above, gives an exact linear solution has been compared with solutions of a linear parabolic equation,

$$2ikA_y = A_{xx}$$

for wave amplitude $A(x,y)$ where surface elevation is $\eta = Ae^{iky - \omega t}$, k is the wavenumber and y is in the direction from the initial line to the focus. As expected good agreement was obtained up to $\alpha = 30^\circ$ the maximum value considered.

Nonlinear solutions were found by numerically integrating the nonlinear Schrödinger equation

$$2ikA_y = A_{xx} - K|A|^2A,$$

as described by Yue and Mei (1980). Some computation was with a simple implicit finite difference scheme, but for most computations a substantially more efficient high-order explicit scheme due to Dold is used. Integration time on a multi-user VAX computer is of the order one minute elapsed time, so results are readily available for any choice of parameters. Figure 2 shows an example corresponding to the case in figure 1(b) depicting the wide focussing region and bordering wave jumps with modulations as described by Peregrine (1983). A useful way of interpreting this type of example is that the focussing part of the wave contributes an extra width to the Mach-stem regions the bounding plane waves would create on their own. However, there are further aspects of this area which are to be described in a more complete account in preparation. For comparison figure 3 shows a linear solution for the same initial conditions.

Experimental measurements

Experiments corresponding to the examples described above were carried out in the Wide Wave Tank at Edinburgh University. This tank has 75 wave paddles each one foot (30cm) wide. A line of 24 wave gauges were used to measure wave height. Any chosen wave pattern was repeated 16 times, on each occasion being moved along by one paddle. In this way a set of 24×16 wave measurements were made without changing equipment position. Under computer control this gave a whole range of experimental results at different steepnesses, and focussing distances with both the wave patterns indicated in figure 1.

Figure 2 A contour plot of a numerical solution for the amplitude of a wave, like that in figure 1(b), with uniform initial steepness $ak = 0.2$, $H/L = 0.06$. This shows the very wide focussing region and the modulated wave jumps at each side. Contours are at 10%, 90% and 170% of the initial amplitude.

Figure 3 The linear theory solution equivalent to figure 2. Contour intervals are the same, but also include 250% and 330% of the initial amplitude, which are not reached in figure 2

In figure 4(a) we show, experimentally measured wave amplitudes for example F. The amplitude of the measured Fourier component at the forcing frequency is shown. This is compared in figure 4(b) with the corresponding linear solution, and the amplitude is clearly much greater than in the experiment. The nonlinear solution in figure 4(c) is much closer to the experimental values. However, there are small scale features in the experiment which suggest the spatial modulation one may expect from a reflected waves. The numerical integration was continued "beyond" the end of the tank where it was reduced by a reflection coefficient corresponding to that measured for plane waves, 0.05 in this case, and the resulting reflected wave added to the wave field of figure 4(c) with the result shown in figure 4(d). A superposition of figures 4(a) and (d) given in figure 5 shows that although there are some differences agreement is satisfactory in many details.

It would be surprising if there were no discrepancy since the nonlinear Schrödinger equation describes weakly nonlinear waves and in this particular experiment the maximum wave steepness is 85% of the steepness of the steepest steadily propagating wave.

Conclusions

Experiment and theory for wave focussing are in good quantitative agreement once reflection from the end of the tank is allowed for. In some experiments waves just reached breaking steepness.

Nonlinear defocussing of water waves is confirmed, but the importance of linear diffraction in defocussing has also been noted and this can be dominant in practical cases.

The experimental tank length is insufficient for wave jumps to be studied but the results give confidence in the equations describing their existence, even for waves close to breaking.

A definitive report of this work is in preparation. The support of the U.K. Science and Engineering Research Council is gratefully acknowledged, and we thank Professor S. Salter for the use of the Wide Wave Tank at Edinburgh University.

CHAPTER 55

OSCILLATORY BOTTOM BOUNDARY LAYER BY LOW-REYNOLDS NUMBER

TURBULENCE MODEL

TOSHIYUKI ASANO¹⁾

HITOMI GODO²⁾

YUICHI IWAGAKI³⁾

ABSTRACT

Characteristics of mean velocity and turbulence properties in oscillatory bottom boundary layers are investigated with low-Reynolds number turbulence model. Since this model is capable to describe the flow field close to the bottom, special attentions are paid on the characteristics of the viscous sublayer. Several interesting results, which coincide with or differ from existing knowledge on steady bottom boundary layers, are presented in particular on the mean velocity profile, turbulent viscosity coefficient and growth of the viscous sublayer.

I. INTRODUCTION

Existing studies for turbulent transport phenomena in coastal processes are mainly based on the eddy viscosity concept. However, it has been recognized that the predictive ability of eddy viscosity models is severely limited. Recently, as the computer technology has been advancing, applications of turbulent transport models to oscillatory flow have received special interest. At present, $k-\epsilon$ model is regarded as the most widely tested and the most applicable two equation model, in which two partial differential equations are used to describe turbulent kinematic energy k and its dissipation rate ϵ .

A few researchers have investigated the applicability of the $k-\epsilon$ model to oscillatory boundary layers (Cousteix et al., 1979; Hayashi and Shinoda, 1979; Shen, 1984), most of these studies dealing only with a high Reynolds number version of the $k-\epsilon$ model. Such a model is no longer applicable to the near bottom region, where the local isotropic condition is not satisfied. Besides, in oscillatory flow, the velocity is so small when the flow direction changes that the turbulence is not always intensive throughout a full period. From above reasons, a $k-\epsilon$ model which accounts for low-Reynolds number effects should be applied to oscillatory turbulent boundary layers.

2) M. Eng., Ministry of Construction (Formerly Post-graduate Student, Kyoto Univ.), JAPAN

3) Dr. Eng., Professor, Dept. of Civil Eng., Meijo Univ., Tenpaku-ku, Nagoya, 468, JAPAN

This study examines the applicability of a $k-\epsilon$ model of low-Reynolds number version to oscillatory boundary layers. From the results obtained, characteristics of both the mean velocity and turbulence are discussed. Furthermore, since the model describes the flow field close to the bottom, comprehensive investigations have been made on the characteristics of the viscous sublayer. The growth of the viscous sublayer under the flow acceleration is investigated in relation to a phenomenon of 're-laminarization' in an accelerated uni-directional flow.

II. $k-\epsilon$ MODEL FOR LOW-REYNOLDS NUMBERS

In order to predict the flow within a viscous sublayer close to the bottom, Jones and Launder (1972, a) have introduced the following extra terms into the standard $k-\epsilon$ model: (1) terms to represent viscous diffusion of k and ϵ , and (2) terms to account for the non-isotropic dissipation process. Furthermore, they have modified some coefficients in the $k-\epsilon$ equations into functions of the turbulence Reynolds number R_T , which is defined with k , ϵ and kinematic viscosity ν as follows:

$$R_T = k^2 / \nu \epsilon \quad (1)$$

For a steady flow, the wall function method (Rodi, 1978) is often used as an alternative to the direct consideration of viscous sublayer properties. In this method the boundary conditions at the bottom are replaced by those immediately outside the viscous sublayer based on empirical laws under the local turbulence equilibrium condition. The method, however, is not applicable to an oscillatory flow since the rate of turbulence generation does not coincide with that of its dissipation at each phase. One of the merits of the low-Reynolds number $k-\epsilon$ model is that all the variables at the bottom can be set to be zero without invoking any empirical knowledge.

III OUTLINE OF THE ANALYSIS

(1) Basic equations

The oscillatory boundary layer equation is given as follows:

$$\frac{\partial(u - u_p)}{\partial t} = -\frac{\partial \overline{u'w'}}{\partial z} + \nu \frac{\partial^2 u}{\partial z^2} \quad (2)$$

where x and z axes are taken along and normal to the flat bottom respectively, t is the time, u is the mean velocity in the boundary layer, u_p is the mean velocity at the outer edge of the boundary layer, and u' and w' are the fluctuating velocity components. The Reynolds stress $-\rho \overline{u'w'}$ is expressed as a product of mean rate of strain $\partial u / \partial z$ and turbulent viscosity ν_T .

$$-\overline{u'w'} = \nu_T \frac{\partial u}{\partial z} \quad (3)$$

The turbulent viscosity ν_T is determined by local values of turbulent kinematic energy k and its dissipation rate ϵ .

$$\nu_T = c_\mu f_\mu k^2 / \epsilon \quad (4)$$

According to Jones and Launder's model (1972,a), the following equations are adopted for k and ϵ .

$$\frac{\partial k}{\partial t} = \frac{\partial}{\partial z} \left[\left(\nu + \frac{\nu_T}{\sigma_k} \right) \frac{\partial k}{\partial z} \right] - \overline{u'w'} \frac{\partial u}{\partial z} - \epsilon - \underbrace{2\nu \left(\frac{\partial k^{1/2}}{\partial z} \right)^2}_{\text{underlined}} \quad (5)$$

$$\frac{\partial \epsilon}{\partial t} = \frac{\partial}{\partial z} \left\{ \left(\nu + \frac{\nu_T}{\sigma_\epsilon} \right) \frac{\partial \epsilon}{\partial z} \right\} - c_1 f_1 \frac{\epsilon}{k} \overline{u'w'} \frac{\partial u}{\partial z} - c_2 f_2 \frac{\epsilon^2}{k} + \underbrace{2\nu \nu_T \left(\frac{\partial^2 u}{\partial z^2} \right)^2}_{\text{underlined}} \quad (6)$$

The underlined terms are included to account for low-Reynolds number effects. After Jones and Launder, the coefficients in Eqs.(4) ~ (6) are given as follows:

$$\left. \begin{aligned} c_\mu &= 0.09, & c_1 &= 1.55, & c_2 &= 2.0, \\ \sigma_k &= 1.0, & \sigma_\epsilon &= 1.3 \end{aligned} \right\} \quad (7)$$

The following expressions proposed by Jones and Launder for f_1 , f_2 , f_μ are also adopted.

$$\left. \begin{aligned} f_1 &= 1.0 \\ f_2 &= 1.0 - 0.3 \exp(-R_T^2) \\ f_\mu &= \exp\{-2.5/(1+R_T/50)\} \end{aligned} \right\} \quad (8)$$

These are a lot of arguments (Hanjalic and Launder, 1976 ; Hosoda and Yokoshi, 1986) concerning the values of the coefficients in Eq. (7) and the functional forms in Eq.(8) even for steady flows. Another problem may arise in applying the values and functional forms proposed for steady flows to oscillatory flows. However, they have been confirmed to be universal at least for various types of steady flow. Furthermore, as seen from Eq.(1), the turbulent Reynolds number R_T varies spatially and temporally with k and ϵ , and it is expected that the vaiations of f_2 and f_μ express the temporal variations of the oscillatory flow properties.

(2) Non-dimensional description of basic equations

To obtain non - dimensional forms of the basic equations, the following variables are introduced:

$$\left. \begin{aligned} \bar{u}_r &= (u - u_p) / \hat{u}_p, & z_r &= z / \delta, & t_r &= \omega t, \\ \tau_r &= -\overline{u'w'} / \hat{u}_p^2, & k_r &= k / \left(\frac{1}{2} \hat{u}_p^2 \right), & \epsilon_r &= \epsilon / \left(\frac{1}{2} \omega \hat{u}_p^2 \right) \end{aligned} \right\} \quad (9)$$

where \hat{u}_p is the velocity amplitude immediately outside the boundary layer, ω is the angular frequency of the oscillatory flow, $\delta = \sqrt{\nu/\omega}$ is related to Stokes length. Now, the system of the equations to be analysed here is as follows:

$$\frac{\partial \bar{u}_r}{\partial t_r} = R^{1/2} \frac{\partial \tau_r}{\partial z_r} + \frac{\partial^2 \bar{u}_r}{\partial z_r^2} \quad (10)$$

$$\tau_r = \frac{1}{2} R^{1/2} c_\mu f_\nu \frac{k_r^2}{\epsilon_r} \frac{\partial \bar{u}_r}{\partial z_r} \quad (11)$$

$$\begin{aligned} \frac{\partial k_r}{\partial t_r} = \frac{\partial}{\partial z_r} & \left\{ \left(1 + \frac{1}{2} R \frac{c_\mu}{\sigma_k} f_\nu \frac{k_r^2}{\epsilon_r} \right) \frac{\partial k_r}{\partial z_r} \right\} \\ & + 2 R^{1/2} \tau_r \frac{\partial \bar{u}_r}{\partial z_r} - \epsilon_r - 2 \left(\frac{\partial k_r^{1/2}}{\partial z_r} \right)^2 \end{aligned} \quad (12)$$

$$\begin{aligned} \frac{\partial \epsilon_r}{\partial t_r} = \frac{\partial}{\partial z_r} & \left\{ \left(1 + \frac{1}{2} R \frac{c_\mu}{\sigma_\epsilon} f_\nu \frac{k_r^2}{\epsilon_r} \right) \frac{\partial \epsilon_r}{\partial z_r} \right\} \\ & + 2 R^{1/2} c_1 f_1 \frac{\epsilon_r}{k_r} \tau_r \frac{\partial \bar{u}_r}{\partial z_r} - c_2 f_2 \frac{\epsilon_r^2}{k_r} \\ & + 2 R c_\mu f_\nu \frac{k_r^2}{\epsilon_r} \left(\frac{\partial^2 \bar{u}_r}{\partial z_r^2} \right)^2 \end{aligned} \quad (13)$$

where R is the Reynolds number defined as follows:

$$R = \frac{(\widehat{u}_p)^2}{\omega \delta} = \frac{\widehat{u}_p a}{\nu} \quad (14)$$

where a is the orbital amplitude at the bottom.

By using low Reynolds number k - ϵ model, the bottom boundary condition is described in the following simple way.

$$\bar{u}_r = -\cos t_r, \quad k_r = 0, \quad \epsilon_r = 0, \quad \text{at } z_r = 0 \quad (15)$$

The upper boundary condition is described as follows.

$$\frac{\partial \bar{u}_r}{\partial z_r} = 0, \quad \frac{\partial k_r}{\partial z_r} = 0, \quad \frac{\partial \epsilon_r}{\partial z_r} = 0, \quad \text{at } z_r = 1 \quad (16)$$

(3) Computational Technique

The vertical grid spacing Δz was determined at $D/600$ (D : the height where shear stress becomes negligible) to obtain sufficient number of grid points in the viscous sublayer. The system of the basic equations (10)~(13) was solved by the Crank-Nicolson implicit scheme. The time increment Δt was $T/2160$. The calculation was continued until the variables at a phase in successive cycles converge. The conditions of calculations are listed in Table 1.

Table 1 Conditions of calculations.

	\widehat{u}_p (cm/sec)	T (sec)	D (cm)	R
CASE-I	30.0	9.8	4.0	1.40×10^5
CASE-II	30.0	15.0	4.0	2.15×10^5
CASE-III	40.0	9.8	5.0	2.50×10^5
CASE-IV	49.9	9.8	7.0	3.87×10^5
CASE-V	49.9	15.0	7.0	5.93×10^5

IV. RESULTS AND DISCUSSION

(1) Mean velocity and turbulence properties

Figure 1 shows profiles of the non-dimensional mean velocity u_R , Reynolds stress τ_R , turbulent energy k_R and its dissipation rate ϵ_R for every $\pi/6$ phase. In Fig.1 and following all figures, the height z is normalized by D ($z_R'=z/D$) instead of δ ($z_R'=z/\delta$). It is found in the results at the phases 0 and π that the heights where the mean velocity reaches its maximum increase with the Reynolds number R ; that is, the velocity gradient decreases with R .

Figure 2 depicts variations of these quantities with phase. The peak values of τ_R , k_R and ϵ_R becomes larger as R increases. The phase lags of the maxima of τ_R , k_R and ϵ_R behind the maxima of the outer velocity decrease with increase in R . It should be noted that the phase of the total shear stress $-\rho\overline{u'w'}+\rho\nu\partial u/\partial z$ close to the bottom goes ahead of the phase of the outer velocity although the phase of the Reynolds stress $-\rho\overline{u'w'}$ lags behind it.

Profiles of the mean velocity u_R are given in Figure 3, where the ordinate is taken in the logarithmic scale. The figure also shows the positions of the outer edge of the viscous sublayer D_L and the overlapped layer d estimated on the basis of Kajiwara's (1968) theory. It is observed in the profiles around the phase 0 and π that the mean velocity shows linear variation in the region $z_R'<D_L/D$, and log-linear variation in the region $D_L/D<z_R'<d/D$. These properties are consistent with the general findings in steady unidirectional flow. Such properties however are not so obvious for the other phases.

(2) Turbulent viscosity coefficient

Figure 4 shows the profiles of the turbulent viscosity coefficient ν_T , which is calculated by the local instantaneous values of k and ϵ shown in Eq.(4). It is found that ν_T increases almost linearly in the region close to the bottom; the phase averaged value of ν_T is almost constant in the region of $0.1<z_R'<0.4$; ν_T decreases with the height in the outer region $z_R'>0.4$.

(3) Transport process of turbulent energy

Figure 5 shows the turbulent energy balance in the oscillatory boundary layer for CASE-I. The symbols Dif, P, ϵ and Ni in the figure denote the turbulence diffusion(1st term of R.H.S. of Eq.(12)), production(2nd term), dissipation(3rd term) and non-isotropic part of the dissipation near the bottom(4th term).

The turbulence production P does not balance with the dissipation ϵ at each phase. The heights for peak values of P and ϵ appear in the range of $z_R'=0.015\sim 0.025$, and the variation of the heights coincide fairly well with the variation of the height of the outer edge of the viscous sublayer which is shown in Figure 6 later. The diffusion term Dif is positive in the region corresponding to the viscous sublayer. The non-isotropic dissipation term Ni takes negative values in the viscous sublayer and tends to zero outside the region.

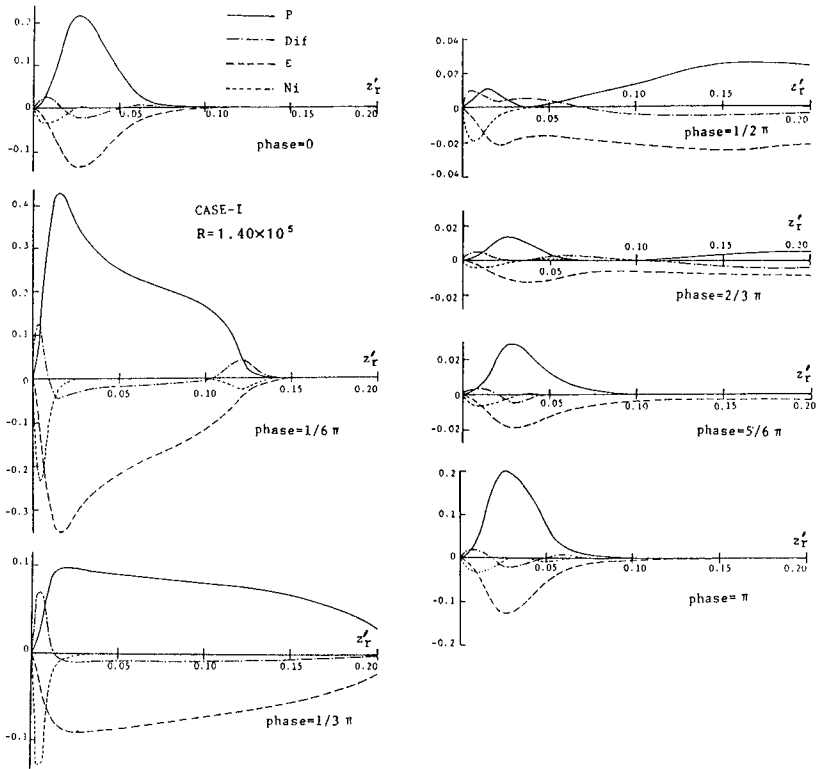

Fig.5 Turbulent energy balance near the bottom.

Fig.6 Variations of the height of viscous sublayer with phase.

Fig.7 Variations of the height of viscous sublayer with phase (at the height where $R_T=5$).

(4) Variation of the height of viscous sublayer

In Kajiura's(1968) theory, the height of the viscous sublayer is assumed to be invariant regardless of phase. However, it is found from the following consideration that the height varies with the phase.

The total shear stress τ_A consists of the viscous and the turbulent shear stresses.

$$\tau_A = \rho(\nu + \nu_T) \frac{\partial u}{\partial z} \quad (17)$$

From Eqs.(1) and (4), ν_T is expressed as a function of the turbulent Reynolds number R_T :

$$\nu_T = c_\nu f_\nu \nu R_T \quad (18)$$

Consequently, the ratio of the viscous shear stress to the total shear stress is a function of R_T . The viscous shear stress occupies 95.7% of the total shear stress when $R_T=5$, and 99.2% when $R_T=1$. If the outer edge of the viscous sublayer is defined as a position where R_T equals 5, the phase averaged height coincides well with that estimated from Kajiura's theory for all cases of the present calculations. The coincidence is not surprising because both this model and Kajiura's theory are based on same experimental knowledge on steady bottom boundary layers.

Figure 6 shows variations of the heights where R_T equals 5 and 1. It is concluded that the thickness of the viscous sublayer varies with the phase and reaches the maximum slightly after the occurrence of the maximum acceleration. In other words, the turbulent energy becomes minimum at the accelerating phases. This is analogous to the re-laminarization in accelerated unidirectional flow(Jones and Launder, 1972b). For an oscillatory pipe flow, Hino et al.(1976) have found experimentally the recovery of a laminar flow condition in the accelerating phases.

Figure 7 shows the variations of the height where R_T equals 5. Comparisons of cases I and II and of cases IV and V, in which cases the velocity amplitudes are same and the oscillation periods are different, show that the maximum thickness of the viscous sublayer increases as the oscillation period increases. In a steady accelerated flow, the thickness of the viscous sublayer increases with the flow acceleration(Jones and Launder, 1972b), whereas the results in Fig. 7 show the opposite feature that the viscous sublayer becomes thicker under smaller flow acceleration. Such difference is attributed to the time required for turbulent energy decay. In the case of short-period oscillating flow, the duration of small flow velocity is not enough for the turbulent energy to attenuate. It can be concluded that the duration of turbulence decaying is a more predominant factor than the effect of flow acceleration for the growth of the viscous sublayer.

V. CONCLUSIONS

1) The variations of the mean velocity and turbulence quantities depending on the Reynolds number have been investigated. The velocity gradients at the phases 0 and π close to the bottom decrease with the Reynolds number. The phase lags of the turbulence quantities behind the outer velocity decrease with increase in the Reynolds number.

2) At the phases around 0 and π , the mean velocity varies in proportion to the height from the bottom in the viscous sublayer and shows the logarithmic variation in the overlapped layer. These are consistent with the general findings in steady flow. However, for the other phases such properties are not so obvious.

3) The turbulence viscosity coefficient increases in proportion to the height in the region close to the bottom, then keeps almost constant in the region $0.1 < z_r' < 0.4$, and decreases with the height in the outer flow region.

4) The thickness of the viscous sublayer varies with phases of an oscillatory flow and becomes maximum when the flow accelerates. The thickness increases with the oscillation period, meanwhile it increases with the flow acceleration in accelerated unidirectional flow.

CHAPTER 56

On the Occurrence of Abnormal Storms and Its Implications on Design Parameters (Statistical Analysis of Same)

Ole Juul Jensen* & P. Klinting**

Abstract

The assessment of design parameters has a fundamental importance for port planning and design of coastal structures. Special emphasis has to be put on the importance of the occurrence of abnormal storms. The authors' experience from investigations of port projects has revealed that on many sites it is storms with unusual tracks or otherwise unusual behaviour that are determinant for the design events. This experience is documented by two case stories. The importance of unusual weather systems is discussed and statistical methods for investigation of such phenomena are discussed.

1. Introduction

The design parameters for ports and coastal structures are usually established by statistical analysis of environmental data on extreme events from measurements or hindcast or a combination of these methods.

Traditionally statistical analysis is based on the application of a probability distribution such as: Gumbel, Exponential or Weibull etc. The theory of statistical distributions requires that the data to be introduced in the statistical analysis all belong to the same stochastic/statistical population. This is usually assumed to be the case if for example the data originate from wave measurements at a specific site.

On some sites, it is, however, evident that two wave regimes occur. This is for example the case for the coasts of the Indian Ocean where both normal monsoon waves and tropical storm waves occur. The two types of waves have clearly

*) Ole Juul Jensen, Head Ports and Marine Structures Department, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

***) Per Klinting, Senior Hydraulic Engineer, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

different origin and may thus be expected to be of different populations as has been documented by many studies. For such sites, it has since long been known by coastal engineers that it is necessary to separate the two regimes of waves when performing statistical analyses. Experience shows that two regimes of storms or storms leading to two statistical populations may also occur on sites exposed to cyclones. (Examples will be presented from Europe and North Africa).

2. Statistical Method for Analysis of Storms

In Ref. /6/, Rosbjerg et al. present the so-called POT-estimation of Extreme Sea States. The POT-method, i.e. peak-over-threshold, considers the distribution of peaks (for example wave heights, H_s) over a preselected threshold level. The following description is an extract from Ref. /6/.

The appropriate threshold is introduced and the recorded wave heights below this level are deleted, the remaining data constitute a partial duration series. This series is likely to represent independent storm events provided that the threshold is reasonably selected. Within each storm the peak value is used for further analysis. The POT-method focus on the relevant statistical variable for extreme events. A basic requirement of further analysis is that selected peaks are independent and identically distributed (i.e. that in any period of time there is the same probability of occurrence of a given wave height. Since for example the waves in the winter and summer season are quite different, it is normally most accurate to separate the two seasons and to consider the waves for example in the winter season, on the Northern Hemisphere October to March, both months included (about 180 days).

Denote either the storm peak itself or some suitable transformation by H'_s and the threshold level by h_* , the distribution function F for H'_s is then introduced as

$$P\{H'_s \leq h \mid H'_s > h_*\} = F(h) \quad (1)$$

Further assume that the occurrence of wave peaks takes place according to a Poisson process with a seasonally varying intensity. This implies that the number of storms per year follows a Poisson distribution with the parameter equal to the integral of the intensity over a year. If this quantity is denoted by λ , the expected number of storms in t years with wave peaks greater than an arbitrary level $h (> h_*)$ becomes

$$v_h = \lambda t (1 - F(h)) \quad (2)$$

The T-year event, h_T , is now defined as the level which, on the average, will be exceeded once per T years. Since this situation corresponds to $v_h = 1$ for $t = T$, the T-year event is obtained by solving Eq. (2) under these conditions leading to

$$h_T = F^{-1} \left(1 - \frac{1}{\lambda T} \right) \quad (3)$$

By use of the above mentioned assumptions implying that the number of storms with wave peaks greater than h in t years follows a Poisson distribution with ν_h as parameter, the distribution for the maximum value of H'_s in t years, $H'_{s \max, t}$ becomes

$$P \{ H'_{s \max, t} \leq h \} = e^{-\nu_h} = e^{-\lambda t (1-F(h))} \quad (4)$$

Now denote by R the probability (the risk) that the level $h_{R, L}$ will be exceeded once or more during a time period of L years (for example the lifetime of the structure). Accordingly, the left hand side of Eq. (4) equals $1-R$ for $t = L$, and a relation between R , L and the corresponding value of T can then be obtained by solving the equation for $h_{L, R}$ and equalizing the expression with Eq. (3). Hereby the following relationship is obtained

$$R = 1 - e^{-L/T} \quad (5)$$

In case of exponentially distributed wave peak exceedances i.e.

$$F(h) = 1 - e^{-\frac{h-h_*}{\alpha}} \quad (6)$$

where the parameter α is equal to the expected value of the exceedances above the threshold value h_* , the expression for the T -year event becomes particularly simple. Combining Eqs. (3) and (6) results in

$$h_T = h_* + \alpha \ln \lambda T \quad (7)$$

which can be used in order to exemplify an approximate method for calculating the standard error of the T -year estimate. In Ref. /6/ it is shown that the approximate standard error of T -year estimate can be written

$$\hat{s}_T = \frac{\alpha}{\sqrt{\lambda}} \left(1 + (\ln \lambda T)^2 \right)^{\frac{1}{2}} \quad (8)$$

It is important to notice that the POT-approach is not limited to the exponential distribution assumption applied above. If another type of distribution, (e.g. lognormal or gamma) is justified, a similar procedure can be applied leading to revised expressions for the standard error of the T -year estimate. For other types of statistical distributions special care should be taken when the threshold level is selected.

3. Storms Caused by Cyclones

In many parts of the world including Europe and the Mediterranean, the severe storms are of the cyclone-type, being roughly circular low-pressure areas with a diameter that may range from hundreds to perhaps two thousand kilometers.

Most storms are associated with cold and warm fronts separating different air masses, but storms also occur when depressions form within the same air mass. The most severe cyclones are normally generated in the Atlantic Ocean east of New Foundland (Ref. /2/) and travel eastwards over the Atlantic Ocean to Europe and the Mediterranean following typical tracks as seen in Fig. 1. These cyclones occur due to unstable waves on the polar front and are therefore always associated with fronts separating different air masses with a difference in temperature. Besides these "Atlantic Cyclones" other cyclones affect Europe and the Mediterranean. Cyclones are sometimes generated on the southwest or southeast side of a cyclone, so-called secondary lows, which sometimes develop into major cyclones (Donn, Ref. /3/).

Many "Atlantic Cyclones" reach the Mediterranean, but in addition cyclones are also generated locally. Ref. /8/ presents an attempt to characterize cyclones in the western Mediterranean after their generation area and track characteristics. The most well known "local" Mediterranean cyclones are those generated within or near the Gulf of Genoa. They usually move southeast across the Tyrrhenian Sea. Fig. 2 from Ref. /5/ shows typical tracks of depressions affecting the western Mediterranean.

Figure 1. Typical tracks of Atlantic cyclones, Ref. /2/.

When making data analyses of wind velocities, wave heights, or water levels it is assumed that the cyclone generated physical data belong to the same statistical popula-

tion. It is the authors' practical experience that in many cases the assumption of all data originating from the same homogeneous data population may be questioned. On some sites, it appears that the most extreme events are due to abnormal cyclone storm tracks leading to unusual weather situations and extreme wind, wave or water level conditions.

When dealing with sites with more than one statistical population of storm waves, it is necessary to separate the analyses into two distributions. A serious problem often arises in this respect, as although there may be sufficient data for the estimate of the distribution for the "normal" waves, the data available for the determination of the parameters of the unusual or abnormal waves will normally be very scarce as shown in the following examples from case studies.

Figure 2. Typical tracks of depressions affecting the Mediterranean.

4. Examples of Abnormal Storm Events

4.1 The Western Part of the Mediterranean (the Coast of Algeria)

The most severe storm situations in the western Mediterranean area are due to Atlantic cyclones entering the Mediterranean after passage of the southern part of France (see Fig. 1 and 2). The cyclones usually follow a track towards ESE passing Italy and propagating further eastwards over Greece and Turkey. For the most severe of this type of cyclones the waves can be relatively high in the western Mediterranean, but due to the relatively fast propagation time of 30-50 km/h the duration of high winds is generally short and hence storms are not fully utilizing the geographical fetch. It appears, however, that the cyclones/depressions causing the largest waves especially on the central and western part of the Algerian coast (see example from the Oran/Arzew area) follow less frequent tracks which are more southerly than the typical patterns described above. Some-

times the cyclones even become stationary as will be seen in some of the following examples.

Based on local information, literature, available measurements and hindcast results from numerical hindcast models, the storms in Table 1 have been found to be among the most severe in the last say 50-60 years. Table 1 shows results of numerical hindcast studies as well.

Table 1. Extreme storms selected for analysis. (Western Mediterranean).

** Wave measurements near Port of Oran, $H_s = 5.5$ m.

- i. The Feb. 1934 storm caused the failure of Jetée Mustapha in Port d'Alger, Ref. /9/ & /10/ in Port of Oran displacement of several blocks on the main breakwater, wave direction NNE. (Note highest waves towards east in Algeria). Wave direction observed, NNE.
- ii. In Port Oran, about 200 blocks displaced. Wave height measured by LCHF, France, at $H_s = 5.5$ m.
- iii. In Port of Oran, damage to the wave wall in several points and some blocks displaced from the armour layer. Wave direction NNE.
- v. Many blocks (in the order of 150) displaced on the main breakwater in Port of Oran, wave direction NNE.
- vi. Failure of the new breakwater in Port d'Arzew el Djedid and damage on other ports in Algeria and Morocco. Wave direction at Arzew/Oran, NNE.

The tracks of all these storms have been analysed and the results are shown in Fig. 3. Figs. 4 and 5 show examples of the results of numerical hindcast studies of the 1967 and 1986 storms.

All the storms are caused by depressions with rather unusual tracks. The centres of the depressions arrived in all cases at or very close to the Algerian Coast. The configuration of the wind field being almost circular with the wind blowing anti-clockwise results in a curved fetch larger than the apparent geographical fetch, see Fig. 4.

It is further interesting to notice that although they all exhibit this common feature, the tracks are all very different. It appears that the tracks of the depressions to a large extent are unpredictable i.e. the atmospheric air flow is highly irregular and once the depressions deviate from their normal track their propagation becomes extremely

Figure 3. Tracks of cyclones for selected storms over the Mediterranean.

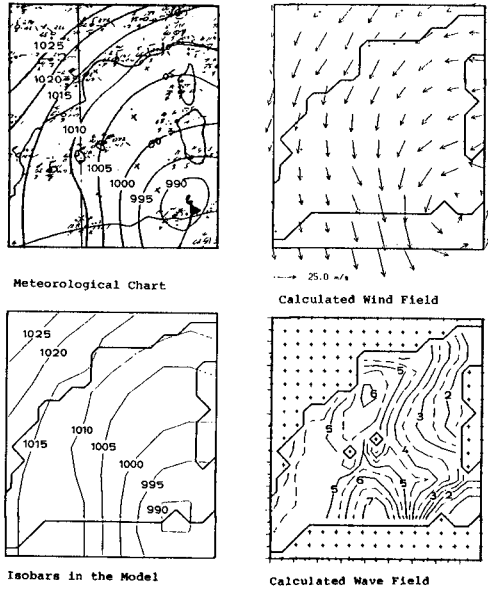

Figure 4. Example of hindcast results of storm on Dec. 10-12, 1967. Situation in the Western Mediterranean on Dec. 12 at 00GMT.

Figure 5. Example of hindcast results of storm on Dec. 27-29, 1980 from Ref. /1/.

complex.

The wave data available from the western part of Algeria show that the storms belong to two populations and further that all the most severe storms occur from NNE and further that they are rather rare. Those storms are associated with the abnormal depressions as seen in Fig. 3.

Figure 6. Weather situation May 1, 1976.

Figure 7. Wave statistics for Arzew El Djedid.

This may be proven by a wave statistics for Arzew El Djedid in the western Algeria. The statistics come partly from wave measurements in the period December 1975 to September 1977 and from the hindcast study shown in Table 1. The most severe storm in the measuring period was due to a low pressure originating from the Gulf of Cadiz (Type B2 in Ref. /8/ propagating straight eastwards through the Strait of Gibraltar (see typical storm tracks in Fig. 2). The situation at the peak of the storm appears on the weather map in Fig. 6. The center of the depression is near the site,

but the fetch to the north is disturbed by the presence of a front running west to east. The statistics appears in Fig. 7. Wave measurements were not available in a form allowing for a POT-analysis. The available data were therefore plotted on logarithmic paper.

It is clear from the statistics that the "normal" wave conditions covered by the measurements did not include any severe storms from NNE of the more stationary type shown in Fig. 3. The statistics for these storms lie above the statistics of the normal storms and two distinct populations of storms are identified although the upper one is not well defined. In this case it is seen to be highly risky to base the long term statistics on two years of measurements where only one regime (population) of the storms occurring on that site is included.

4.2 Extreme Waves from SE in the Faroe Islands

The main harbour in the Faroe Islands is Torshavn. This harbour is exposed to waves from SSE and NE. Torshavn is partly sheltered by the island of Nolsoe, see Fig. 8, which shows the position of Torshavn and of the wave recording station, East, mentioned in the following.

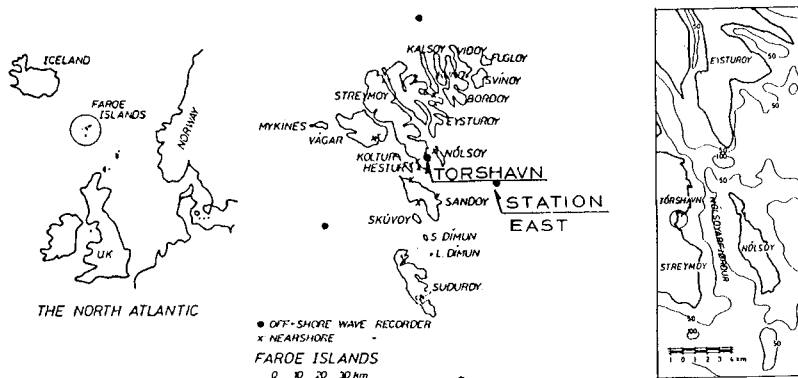

Figure 8. Location of Torshavn.

The design storms occur from SSE and they are associated with the occurrence of unusual depressions, unusual not with respect to the storm track but in the sense that they become stationary. The two most severe storms from SSE since 1930 occurred on Jan. 15-19, 1972, and on Jan. 21-22, 1984. Both storms created very large waves from SSE due to a depression over Ireland that could not move eastwards because of blocking high pressure over Norway. The depression consequently became stationary.

In Figs. 9 & 10 the weather situation for the two storms is described by weather maps.

A detailed survey of the weather maps of storms from SSE in the period 1930 to 1972 has revealed that no other storms in this period are as severe. The two storms caused offshore waves in the order of $H_s = 11$ m. In the storm of Jan. 21-22, 1984, the waves were measured at $H_s = 11.3$ m at the peak. A desk hindcast study using the SMB-method has shown that the third and fourth most severe storm since 1930 occurred in 1959 ($H_s \sim 9.5$ m) and 1941 ($H_s \sim 9.0$ m). Both storms were of the same type as 1972 and 1984, but with lower wind velocity. In Fig. 11 a POT analysis of measurements from station East is shown for the period Oct. 1980 to April 1987. The threshold level used is $H_s = 5.0$ m.

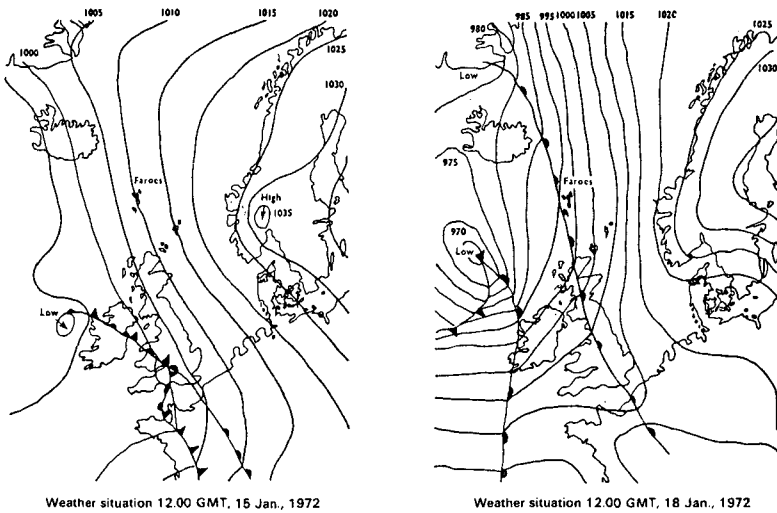

Figure 9. Weather maps of 1972 storm.

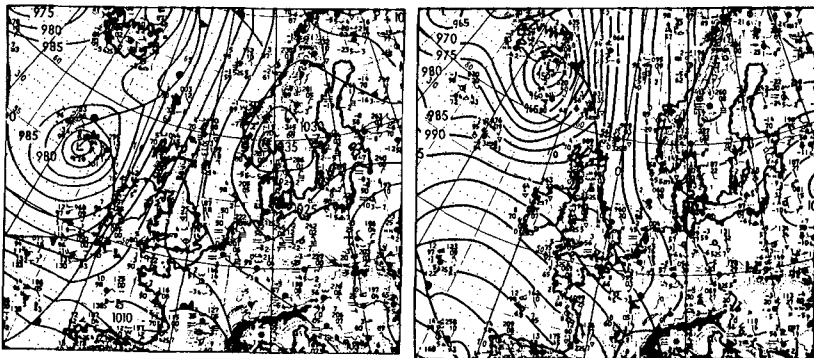

Figure 10. Weather maps of 1984 storm.

Figure 11. POT analysis of wave measurements. Station East.

It is seen that the data for "northern" and "southern" directions are following the distribution except the storm of January 1984, which falls well above the rest of the distribution. In order to see whether the distribution is actually a double distribution composed of two distributions the available information on the storms has been plotted in Fig. 12 where the abscissa has been changed to show the number of storms per year instead of the probability. The storms in question appear in Table 2. In this presentation the two severe storms of 1972 & 1984 are still above the distribution of measured data while the two storms of 1941 & 1959 are below.

Table 2 Ranking of the four most severe storms.

Ranking	Storm	H_s (m)	Return Period years $\frac{n+1}{m}$	Probability of Occurrence per year $\frac{m}{n+1}$
1	1984	11.3	59	0.017
2	1972	11.0	29	0.034
3	1959	9.5	19	0.05
4	1941	9.0	14	0.07

It is seen that also in this analysis the wave data indicate two distributions. The analyses were performed under the assumption that the wave climate has not changed in the period 1930 to 1987, while from other sources there are certain indications from the Northern Atlantic and the North Sea that the wind and waves have been more severe in the last 10-15 years.

Figure 12. Statistics of number of storms per year.

5. Conclusions

The paper has shown that the occurrence of storms and high waves and water levels at many sites is highly complex and that it can be risky to assume all data belonging to one statistical population.

It is consequently the hope that the paper will encourage meteorologists and coastal engineers to embark on detailed co-operation for improving the understanding of the occurrence of abnormal storm events in order to provide more reliable assessments of extreme design events. The above are only a few examples of sites where mixed distributions occur. It is the author's feeling that on many sites, the same is the case.

The meteorological data bases that are set up these years and the advanced wave hindcast techniques on numerical models now available enable more profound studies to determine more accurate design data for man made marine and maritime structures and for assessing the risk for existing installations. The paper has shown the necessity for such investigations.

6. Acknowledgement

The authors would like to express their appreciation to the Laboratoire d'Etudes Maritimes (LEM) for cooperation on hydraulic studies for Algerian Projects and to the Faroe Islands Harbour Authorities (Landsverkfrødingurin) for providing data and making the POT-analysis of wave data from Station East at Faroe Islands.

CHAPTER 57

WAVE OVERTOPPING ON RUBBLE MOUND BREAKWATERS

Pierluigi Aminti *

Leopoldo Franco **

ABSTRACT

The paper gives the results of an extensive series of hydraulic model tests carried out in a random wave flume, in order to study the effects on wave overtopping of the main geometric parameters of a typical rubble mound breakwater with crown wall. The results have been compared with those from other studies and analyzed with different methods. Generalized design diagrams and formulae for the prediction of overtopping discharges are finally given for a large number of popular breakwater configurations.

1. INTRODUCTION AND BACKGROUND

Wave overtopping is one of the most important hydraulic processes affecting the design of a breakwater, especially when a crown wall protects a quay or a reclamation. However, most research work on breakwaters just deals with the hydraulic stability and structural response of the primary armour. Still too limited information is available to the engineers for predicting the overtopping discharges and then checking against well established admissible values. In particular no reliable methods allow the fundamental design selection of the breakwater crest elevation and configuration to be effective against wave overtopping.

Model tests have often been carried out with regular waves, with consequent underestimation of the overtopping rates, which are mainly governed by the highest waves in the train.

Even the current prediction method given by the Shore Protection Manual (SPM, 1984) is based on early tests with monochromatic waves. In this method the overtopping discharge is given by a formula

* Associate Professor of Marine Civil Engineering, University of Florence, Via S.Marta 3, Florence, Italy

** Associate Professor of Coastal Engineering, Polytechnic of Milan, Piazza Leonardo da Vinci 32, Milan, Italy

related to the potential runup on a corresponding infinite slope. Then many problems arise as pointed out by Ahrens and Heimbaugh (1986). Moreover it should be observed that the runup computations themselves may be wrong. In fact in the SPM the runup on a rough slope is linearly related, by a simple reduction factor, to the runup on the equivalent smooth slope, while extensive random wave model tests reported by Allsop, Franco and Hawkes (1985) have shown a quite different behaviour of the two types of slopes for variable Iribarren numbers.

Some simplified theoretical approaches for the evaluation of overtopping discharge have been proposed by various Japanese researchers and recently by Jensen and Juhl (1987). These Authors also report on the very few existing field measurements carried out in Denmark and in Japan, which seem to agree with model test results when the experiments are conducted with irregular waves.

The Japanese prototype measurements reported by Fukuda, Uno and Irie (1974) were also used to provide the only available rough and conservative guidelines for acceptable overtopping discharges or intensities. In general, according to them, inconvenience for persons or vehicles (passing 3 m behind the crown wall) arise when the mean overtopping discharge per unit length of breakwater $\frac{Q}{3}$ reaches about 10^{-6} m³/s m, while danger occurs if Q exceeds $2 \cdot 10^{-5}$ m³/s m. These apparently low figures account for the fact that the danger levels are actually determined by the single largest overtopping waves which, due to the high irregularity of the physical phenomenon, can produce peak intensities a few hundreds times greater than the average intensity.

Most information is still obtained from laboratory work, which however often concerns seawalls in shallow water, such as the random wave investigations performed by Owen (1980) and by Ahrens and Heimbaugh (1986).

With reference to rubble mound breakwaters in relatively deep water, Jensen (1984) collected results from irregular wave model tests carried out at DHI for several different projects (some including the wind effect too); the set of graphs, later reanalyzed by Jensen and Juhl (1987), is useful but limited to the specific geometries and conditions of the tested breakwaters.

The lack of reliable and complete design guidelines then stimulated the Authors to begin in 1986 a systematic experimental research program: the preliminary results given by Aminti and Franco (1987) are now supplemented by numerous additional tests with new configurations, whose results are presented here in a more effective and general form.

At the final preparation of this paper it was possible to examine the results of a similar basic research program conducted at HR, Wallingford by Bradbury and Allsop (1988). They studied the effect on overtopping discharge of various crown wall and armour crest configurations with smooth and rock armoured slopes at a fixed angle (1:2). The satisfactory comparison of the hydraulic performance of the similar structures then suggested a consistent and general form of analysis and presentation of the experimental data, as shown in par. 3.

2. TEST EQUIPMENT AND PROCEDURE

The model tests were conducted in the 48 m long, 0.80 m wide and 0.80 m deep wave flume of the Florence University's hydraulic laboratory. The flume is equipped with an oleodynamically actuated piston-type wavemaker, with a random wave input signal obtained by filtering a white noise (Aminti, Liberatore and Petti, 1984).

A Jonswap type spectrum was reproduced with a significant wave height $H_s = H_{1/3,u} = 0.136$ m and a mean period $T = \bar{T} = 1.33$ s, measured by capacitive gages at the model structure location before its construction, having an absorbing beach at the end of the flume.

The water depth at the model section was 0.40 m (with a constant foreshore gradient of 1/50) to ensure non-breaking wave conditions before the structure. The duration of each test, twice repeated, was 10 minutes (one hour prototype). A 1:36 Froude undistorted scale was in fact used.

Only one random wave condition was considered in order to reduce the number of tests to the manageable figure of 270 and focus the attention to the influence of breakwater geometry and construction.

The typical model test section is shown in fig.1. The usual composition of the relatively impermeable core and of the filter layer were not changed, while the other structural parameters affecting the overtopping performance were varied as follows, in order to simulate the most popular prototype configurations (for symbols see fig.1):

FIG.1: Typical model test section with notation of geometric parameters

- 1 - Relative crown wall freeboard (to S.W.L.): $F/H = 0.60+2.00$
- 2 - Relative armour crest height (to S.W.L.): $h_a/H_s = 0.60, 0.75, 1.05$
- 3 - Relative armour crest berm width: $b/H_s = 1.10, 1.85, 2.60$
- 4 - Seaward slope angle: $\cot \alpha = 1.33, 1.50, 2.00$
- 5 - Type of armour unit: rock, cube, tetrapod

It should be noted that:

- F and h_a are not totally independent, being $F/h_a \geq 1.0$ in all tests;
- the three ratios b/H_s approximately correspond to horizontal armour crest berms of 3-5-7 units respectively;
- the armour units had random placement with the typical recommended

densities and their weights determined as to guarantee stability under the test conditions;

- the parameter B/H_s , which represents the breakwater width, is dependent on b , h_s^a and $\cotg\alpha$ and varies between 1.9 and 4.7;
- due to the marginal influence of the slope angle the analysis was then restricted to the extreme values of $\cotg\alpha = 1.33$ and 2.00 (slopes $3/4$ and $1/2$).

In each tests the following measurements were taken:

- a) number of overtopping waves (visually counted)
- b) average overtopping discharge (collected in a graduated cylinder through a 0.1 m wide prismatic pipe placed behind the crown wall)
- c) jet falling distance (visualized by the water quantities contained in five consecutive trays).

However, the latter measurements were not considered accurate enough to derive reliable quantitative results, also bearing in mind the neglected wind effect and the incorrectly scaled simulation of the air-drop interaction. It was just possible to observe qualitatively the same exponential decay found by Jensen and Juhl (1987).

In consideration of the practical design needs the attention was concentrated on the model measured overtopping discharges Q ($m^3/m s$) averaged over the time interval for one metre of breakwater length.

3. PRESENTATION OF MODEL TEST RESULTS

An open question is the selection of the proper parameters for the presentation of the experimental data. The above mentioned Authors use different dimensionless frameworks (and often different symbols) to generalize the relationship between the overtopping discharge Q and the crown wall freeboard F , which is the most relevant geometric factor.

A significant summary of this variety of coefficients is given in tab.1. In Jensen and Juhl (1987) the parameter Q was not even made dimensionless, because of the difficulty in deriving a unique universal factor (the previously used factor QT_m/B^2 is no more regarded correct).

Even the proposed empirical relationships are not consistent and generally have one of these two different forms:

$$Q^* = A \exp(-BF^*) \quad (1)$$

$$Q^* = A (F^*)^{-B} \quad (2)$$

where Q^* and F^* are the dimensionless discharge and freeboard, A and B best fit coefficients.

The data obtained from the present tests was therefore analyzed using a variety of methods. In general a higher correlation was obtained with equation (2), as shown by the linear regressions of the logarithms of Q^* and F^* (in agreement with Bradbury and Allsop, 1988).

The dimensionless parameters which are regarded most effective and of simplest practical use are Q^* ($=Q/g T_m H_s$) and F/H_s . However, due to the unique wave test condition, all graphs have been drawn with double scales/parameters for both the discharge (Q and Q^*) and the freeboard F/H_s and $F^* = (F/T_m \sqrt{g H_s}) \cdot (F/H_s)$ in order to make an easier comparison with the recent data of Bradbury and Allsop (1988) and to

AUTHOR	DIMENSIONLESS DISCHARGE Q*	DIMENSIONLESS FREEBOARD F*
Owen (1980)	$\frac{\bar{Q}}{\bar{T} g H_s}$	$R^* = \frac{R_c}{\bar{T} \sqrt{g H_s}}$
Jensen (1984)	$\frac{Q T_z}{B^2}$	$\frac{H_s}{\Delta h}$
Ahrens and Heimbaugh (1986)	$\frac{Q}{\sqrt{g H_{mo}^3}}$	$F' = \frac{F}{(H_{mo}^2 L_p)^{1/3}}$
Bradbury and Allsop (1988)	$\frac{\bar{Q}}{T_m g H_s}$	$F^* = \frac{R_c}{T_m \sqrt{g H_s}} \cdot \frac{R_c}{H_s}$
Sawaragi, Deguchi Park (ICCE, 1988)	$\frac{\bar{Q}}{\sqrt{g L H^2}}$	$\frac{H_c}{H}$
Note: $R_c = H_c = \Delta h = F =$ crown wall freeboard		

TAB.1: Summary of representative overtopping parameters proposed by various Authors

facilitate their general design use.

The large number of tested variables allows the plotting of several diagrams outlining the influence of each variable with different configurations. Due to space limitations it was decided to plot all data within six graphs for fixed armour type and slope angle, thus emphasizing the most relevant effects of variable freeboards and armour berm widths (figs. 2 A-B, 3 A-B, 4 A-B).

Then, the marginal influences of variable armour type or slope angle (for fixed berm widths) can be both shown by just one representative typical diagram (fig. 5 A-B). For a better analysis of the effect of the armour type, the configuration with minimum path to be run by the overtopping wave was selected ($b/H_s = 1.1$, slope 3/4). Similarly the influence of the slope could be better detected for the configuration with shortest berm and most controlled armour units (tetrapods).

It should be noted that the data scatter is partly due to the different values of h_a tested for the same F. However all regression lines have very high correlation coefficients, with a minimum of 0.89.

TAB.2: Summary of empirical coefficients

The analysis of the plotted results leads to the following main observations:

- 1) Increasing the freeboard of the vertical wall (F) has the greatest effect in reducing the overtopping discharge (according to a power law).
- 2) Increasing the armour crest berm width (b) also produces a reduction of discharge, which is more evident and consistent with steeper slopes and with tetrapod armour units.
- 3) Shallower slopes (1:2) can also reduce overtopping, probably due to the longer rough path; this slope-effect is confirmed by the results from Jensen and Juhl (1987) and is more evident with narrow armour berms.
- 4) Tetrapods have a slightly better hydraulic performance than rock and cubes; the rock armour seems to give less overtopping discharges than cubes except for extreme events.
- 5) Increasing the armour crest elevation (h_a) often results in a reduction of discharge, but the trend is not clearly defined and no plot is therefore given.

It can be observed that in order to satisfy the existing safety guidelines proposed by Fukuda, Uno and Irie (1974), within the test

conditions, the relative crown wall freeboard F/H_s generally ranges between 1.0 and 1.4. The conservative nature of these guidelines may be compensated by the neglected effects of onshore winds, oblique wave attack and by scale effects.

It was possible to check just a few test results against data points for similar conditions reported by Jensen and Juhl (1987) in their figures 12-13: the measured discharges compare quite well.

A fair agreement can also be found with the results obtained by Bradbury and Allsop (1988), although the overtopping prediction seems to give slightly larger values than those reported for their most similar configurations n.8 and 10. Moreover their assumption of slope 1/2 being the worst case is contradicted by the present test results.

Finally another regression analysis was carried out with all data, in order to relate the overtopping discharge Q to the percentage of overtopping waves P . Again the best fit was given by an equation of the form $Q = C P^D$ (C , D empirical coefficients): the discharge increases rapidly as the number of overtopping waves increases. However the data scatter and the limits of tested conditions don't allow the derivation of a useful relationship of general validity.

4. CONCLUSIONS

The results of several random wave model tests for variable configurations of breakwater superstructure have shown the influence of various geometric parameters on the overtopping discharge and allowed the presentation of a set of graphs useful for preliminary design purposes.

The prediction model providing the best description of the overtopping performance is based on an equation of the form $Q^* = A (F^*)^{-B}$, where the dimensionless discharge Q^* rapidly increases with decreasing relative crown wall freeboard F^* .

However, representative universal dimensionless factors are still to be defined. Other geometric parameters have shown a significant effect on the overtopping, especially the width of the armour crest berm. The change of seaward slope angle also has some influence, while different armour types have a quite similar behaviour (within the test conditions). The inclusion of these effects into a more complex comprehensive factor might be possible when more tests will be conducted with different wave conditions (wave periods in particular), and by combining the data from various Authors.

It is then hoped that a normalization of definitions and symbols of the typical breakwater geometric parameters will be agreed internationally, as recently done by IAHR-PIANC for the wave parameters.

Further work should also be addressed to the definition of more accurate, detailed and universal design criteria, i.e. admissible overtopping discharges for different degrees and destinations of the protection. More measurements of individual overtopping discharges should be carried out both in model and prototype conditions, together with the assessment of their consequences on variable targets.

CHAPTER 58

Reflections from coastal structures

N W H Allsop+
S S L Hettiarachchi*

Abstract

Wave reflections at and within a coastal harbour may make a significant contribution to wave disturbance in the harbour. Reflected waves may lead to danger to vessels navigating close to structures, and may reduce the availability of berths within the harbour. Wave reflections may also increase local scour or general reduction in sea bed levels.

In the design of breakwaters, sea walls, and coastal revetments, it is therefore important to estimate and compare the reflection performance of alternative structure types. In the use of numerical models of wave motion within harbours, it is essential to define realistically the reflection properties of each boundary. This paper presents results from a study of the reflection performance of a wide range of structures used in coastal and harbour engineering.

1 Introduction

The importance of wave reflection from coastal and harbour structures has historically been given relatively little weight in the design of harbours or of coastal protection schemes, despite the problems that may arise from the cumulative increase in wave energy. Typically, increased wave action due to reflections may lead to:

- a) danger in navigating vessels through steep seas arising from the interaction of incident and reflected wave trains, this often occurs at harbour entrances;
- b) increased berth down-time within the harbour arising from unacceptable vessel motions during loading or unloading;
- c) damage to vessels, moorings, or fenders, arising from increased mooring forces;
- d) increased wave velocities, and hence shear stresses, at the structure toe, leading to potentially greater local scour or sea bed erosion.

This paper summarises results from a study of the reflection performance characteristics of a wide range of structure types used in

coastal and harbour engineering. The report on that study (Ref 1) discusses the design and use of wave absorbing structures, and derives values of empirical coefficients for the prediction of reflection performance in random waves. Some of the results of that study have been employed in the derivation of appropriate boundary conditions for the numerical modelling of wave disturbance in harbours (Ref 2).

2 Wave absorbing structures

Coastal structures devised to absorb or dissipate wave energy may be considered under three main categories:

- a) non-porous, slopes;
- b) armoured, porous, slopes;
- c) porous vertical face or faces.

Each of these structure types will dissipate some proportion of the incident wave energy and will generally reflect the greatest part of the remainder. At the extremes the reflection performance of such structures may be compared either with that of a vertical wall, for which the proportion reflected approaches unity, or with a gently sloping yet porous beach for which the energy reflected approaches zero.

A number of different mechanisms may be employed to absorb or dissipate wave energy. These will depend upon the properties of both the structure, and of the incident waves. A number of empirical methods have been developed to aid the identification of wave behaviour at such a structure. Of these a single parameter of particular relevance to wave action on sloping structures is the Iribarren number, I_r , sometimes known as the surf similarity parameter, introduced by Battjes. For regular waves:

$$I_r = \tan \alpha / (H/L_0)^{1/2} \quad (1)$$

On non-porous rough slopes wave run-up and reflections are generally similar to those on the equivalent smooth face, but with some further energy dissipation due to the greater frictional and turbulent losses.

The behaviour of waves at an armoured rubble slope is different in that a significant depth of porosity in the armour and under-layers, and perhaps the core, is available for energy dissipation. Much of the incident wave energy may be converted to flows over and within the armour and under-layers, thence being dissipated in turbulence within the voids. Some of this energy may be converted to pumping water into the mound, particularly under long period waves when the phreatic surface inside a rubble mound may be considerably elevated. Energy from such flows will be substantially lost in frictional flow within the porous rock layers.

The advantages of vertical face structures over those with sloping faces lie in the efficient use of space, economy of material, and the ability to moor vessels alongside. These factors are of considerable importance to the harbour engineer. Problems due to the reflections from solid vertical faces suggest a number of alternative forms of construction. Porous vertical walls must dissipate wave energy in a gradual manner to avoid undue reflections. Significant

energy absorption will require a reasonable depth of structure in relation to the incident wave length. Examples of types of structures to do this include:

- a) cribwork or gabion walls;
- b) piled wave screens;
- c) perforated caissons; and
- d) stacked voided blockwork.

Each of these structure types offer some considerable advantage over sloping face structures in the greater utilisation of the harbour area. In general, however only the last three types (b)-(d) are likely to be used in harbours.

The simplest wave absorbing vertical walls used in harbours are single or multiple wave screens. These may be formed of closely spaced elements such as steel or timber piles, concrete or timber planks, or other pre-cast concrete elements. In a single screen porosities, n_a , of around 5-20% will commonly be used. The screen elements are generally supported on a steel or timber pile structure. This may allow the provision of two or more screens on the same structure. Examples of the design and/or construction of single or double wave screens are described by Gardner et al (Ref 3), and Hutchinson & Raudkivi (Ref 4).

A single screen alone will absorb or dissipate relatively little of the incident wave energy. Most will be either reflected or transmitted. Certain arrangements of two or more screens may be devised to yield acceptable levels of reflection, whilst restricting wave transmission.

The simplest multiple screen in general use incorporates a perforated front screen separated from a solid rear screen by a spacing B . For B equal to around 0.25 of the local wavelength L_s , waves transmitted through the front screen will reflect off the rear screen to return to the front screen exactly out of phase with the next wave. The resulting interference leads to a significant dissipation of wave energy between the two screens, and hence yields particularly low reflections. For wavelengths other than the optimum of $4B$, the reflection performance will be less good. By judicious choice of screen porosity n_a , and screen spacing B , acceptable reflection performance may be obtained over a reasonable range of wavelengths, or wave periods.

Similar principles may be used in the design of pre-cast concrete caissons with a perforated front face. Such caissons will incorporate at least two chambers: one open to wave-induced flows; the other filled with sand or concrete to ensure adequate resistance to sliding or overturning. The front face may be perforated by horizontal or vertical slots, or by circular holes. The perforations may extend only part depth and/or vary in spacing with depth. The size and shape of the void chamber may vary, as may its complexity.

Some of the hydraulic characteristics of the wave-absorbing caisson can be obtained on a smaller scale by the use of voided concrete blocks. These may be stacked vertically to form breakwaters, sea walls, or in some instances quay walls. A variety of these blocks have been developed, and most have been widely patented. Examples of stacked voided blocks are:

Igloo	Perforcell
Neptune	Pilock
Cross-hollow	Trium
Warock	Diaer
Monobar	Tine
Arc	H. W.

3 Calculation of reflection performance

The prediction of the level of reflected wave energy has been investigated using both theoretical and of experimental studies. Methods to allow predictions reflection performance have been identified using three main approaches:

- a) empirical equations;
- b) mathematical modelling;
- c) graphical presentation of model test results.

Empirical equations and coefficients have been developed from the results of hydraulic model tests. Most of the available literature is based on studies with regular waves and often assumes the validity of linear wave theory. Apart from some model tests pertaining to particular structures, few detailed studies have been performed using random waves. The following general empirical equations have been presented:

$$C_r = f (a Ir^b) \quad (2)$$

$$C_r = a Ir / (Ir + b) \quad (3)$$

$$C_r = a Ir^2 / (Ir^2 + b) \quad (4)$$

$$C_r = a (1 - \exp (-bIr)) \quad (5)$$

where a and b are empirical coefficients.

For random waves, the significant wave height, H_g , and the wave length corresponding to the period of peak energy density, L_p , are used to define a modified Iribarren number Ir' :

$$Ir' = \tan \alpha / (2\pi H_g / g T_p^2)^{\frac{1}{2}} \quad (5)$$

Smooth slopes

Much of the most useful information for the prediction of wave reflection from non-porous sloping structures is presented by Seelig & Ahrens, a summary of which was later given by Seelig (Refs 5 and 6). For simple smooth slopes Seelig advocates the use of equation 4 with values of a = 1.0 and b = 5.5, giving:

$$C_r = \frac{1.0 Ir^2}{Ir^2 + 5.5} \quad (6)$$

Seelig also compares the use of equation 4 with coefficients a = 1.0 and b = 6.2 for a smooth slope, with measured data, and the other empirical equations, Figure 1.

Fig 1 Reflection performance of smooth slopes, after Seelig

Results from earlier studies at Hydraulics Research have been re-analysed. Measurements were made of random wave reflections from smooth slopes of 1:1.33, 1:1.5 and 1:2.0. For conditions within the range $3 < Ir' < 6$, prediction equation 4 with $Ir = Ir'$, and empirical coefficients $a = 1.08$ and $b = 5.7$, provides a good fit to the experimental data:

$$C_r = \frac{1.08 Ir'^2}{Ir'^2 + 5.7} \tag{7}$$

These results are illustrated in Figure 2. It is noted that the predicted values for C_r using these coefficients and the modified Iribarren number, Ir' , are slightly greater than those recommended by Seelig.

Fig 2 Reflection performance of smooth slopes under random waves

Rough slopes

The reduction in the reflection coefficient due to the placement of rockfill on the surface of an otherwise impervious structure has been investigated by Seelig and Ahrens. For a revetment with layers of armour rock, they recommend values of empirical coefficients to correct predicted reflection coefficients for smooth sloping surfaces using equation 4.

Porous sloping structures

Generally rubble breakwaters, sea walls and revetments will dissipate significantly more wave energy than the equivalent non-porous slope. The principal structure parameters governing this are the armour, underlayer, and core porosities, permeabilities, and available void volume.

For rock armoured structures, Seelig argues that the calculation method based upon the use of equation 4 may be further extended by defining $a = a_1 a_2 a_3$, where the empirical coefficients a_1 , a_2 , and a_3 take account of relative water depth, thickness of armour and underlayer, and relative armour size. The method is based on successive modifications to the expression for smooth slopes. Alternatively, Seelig suggests that quick and conservative estimates may be made by using equation 4 with $a = 0.6$, $b = 6.6$.

Concrete armour

A sea wall or breakwater armoured with concrete armour units will exhibit a reflection performance that is essentially similar to that of the equivalent rock armoured slope. Some types of concrete armour unit are more open and permeable to wave action than rock armouring, and reduced reflections may therefore be expected. Conversely bulky armour units such as cubes have sometimes been placed very closely with low armour layer porosity, and hence higher reflections will result than might be predicted.

Measurements of the reflection performance of laboratory slopes armoured with concrete armour units have been re-analysed for this study. The results are presented in Figures 3-6 as values of reflection coefficient C_r against Iribarren number Ir , or Ir' for random waves. Empirical equations of the form of equation 4 have been fitted to the data and the results are summarised below:-

Armour	Wave	Range of slope angles	Range of Ir or Ir'	Coefficients in equation 4	
				a	b
Dolos	Regular	1.5-3.0	$1.5 < Ir < 5.5$	0.56	10.0
Cobs	Regular	1.33-2.5	$1.5 < Ir < 4.5$	0.50	6.54
Tetrapods or Stabits	Random	1.33-2.0	$2.5 < Ir' < 6.0$	0.48	9.62
Sheds or Diodes	Random	1.33-2.0	$3.0 < Ir' < 6.0$	0.49	7.94

An alternative use of either rock or concrete armouring is in a mound placed against a vertical wall. Such protection will significantly reduce the reflections, as well as protecting the wall from wave impact. Rock or concrete armour may also reduce

Fig 3 Reflection performance of Dolos armoured slopes, regular waves

Fig 4 Reflection performance of Cob armoured slopes, regular waves

Fig 5 Reflection performance of Tetrapod or Stabit armoured slopes, random waves

Fig 6 Reflection performance of Shed or Diode armoured slopes, random waves

overtopping. An example of protection to an existing sea wall was discussed at a seminar (Ref 7). Measurements of reflections for three sections are presented in Figure 7. The existing wall, section 1, has high reflections. At low water levels, wave breaking in front of the wall has reduced the reflections to around 0.65. At the higher water levels C_r approaches 0.9. The reflection performance of the alternative rock protection, sections 2 and 3, varies with water level, and particularly with the relative position of the berm formed by the crest of the rock protection. For those water levels close to the crest level of the rock the reflection coefficient reaches minimum values with C_r around 0.20-0.30. When the waves reflect from the armour slope the performance deteriorates slightly with C_r generally nearer 0.4.

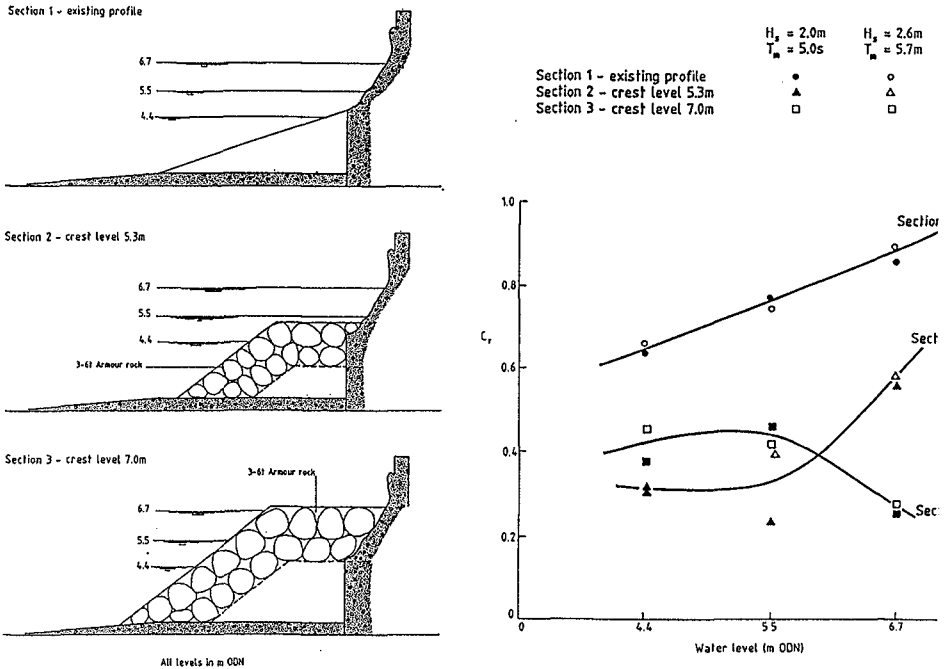

Fig 7 Performance of rock protection to existing wall

Vertically faced structures

Pervious wave screens or pile arrays have been much studied by researchers concerned with wave energy transmission, dissipation, and reflection. Results from model tests for single wave screens have been presented previously by Kakuno (Ref 8) and Allsop & Kalmus (Ref 9). Example summaries of their results are shown in Figure 8.

Fig 8 Reflection and transmission for single wave screens

In many instances in coastal and harbour engineering, wave-absorbing structures such as quays or sea walls are built with a solid rear face. The performance of the double wave screen used by Gardiner et al (Ref 3) at Plymouth has been described by Allsop & Kalmus (Ref 9). A simple summary of the effects of front screen porosity, n_a , screen spacing, B , and local wave length, h_s , on the reflection performance is shown in Figure 9. These results, derived from measurements in random waves, seem to indicate that the optimum performance is given by a front screen of porosity, n_a between 0.15 and 0.25. At the lower end of this band the range of wavelengths that give low reflections, say $C_r < 0.4$, is significantly wider than for a screen of porosity around 0.3.

It should be noted that a full description of the processes of wave reflections from a structure would require details of the reflection coefficient function with frequency, of the effects of wave breaking, particularly in shifting energy over frequencies, of the phase shift at reflection, and of the effects of oblique wave/structure interactions. The methods presented in this study therefore represent a considerable simplification of the processes involved. The reader is therefore advised to use the results with some care and circumspection.

Fig 9 Wave reflection performance of wave screen with impermeable rear wall

4 Conclusions and recommendations

The reflection performance of a range of structure types have been examined and quantified. A general empirical expression of form advanced by Seelig has been used to describe the reflection characteristics of permeable or impermeable slopes. Results from random wave model tests have given values for the empirical expression for permeable slopes armoured with Dolos, Tetrapod, Stabit, Cob, Shed, and Diode, units, and for smooth impermeable slopes. During this study it was not however possible to quantify the reflection performance of rock-armoured slopes under random waves. It was therefore recommended that a systematic series of random wave model tests be conducted to quantify the effect of structure slope, armour size, armour thickness, and berm configuration on wave reflections. (These tests have been conducted, summer 1988, and will be described in a future report, Reference 10).

Vertically faced structures offer the harbour designer potential space saving and enhanced use over structures with sloping faces. This study has reviewed the reflection performance of a range of caisson and voided block systems. This paper has summarised the reflection performance of single and double wave screens under random waves.

5 Acknowledgements

This paper summarises work conducted by Hydraulics Research for the British Overseas Development Administration. Dr Hettiarachchi was on study leave from the University of Moratuwa, and was supported by a bursary from Hydraulics Research during the period of this work.

CHAPTER 59

SEAWALL OVERTOPPING MODEL

John P. Ahrens, Aff. M.¹ and Martha S. Heimbaugh, A.M.,² ASCE

ABSTRACT

Results from an extensive series of laboratory tests of irregular wave overtopping for a number of seawall and seawall/revetment configurations is presented. Data for 13 configurations has been collected and grouped into 7 data sets representing relatively similar geometrical characteristics. All data sets showed an approximately exponential relationship between the overtopping rate and a dimensionless freeboard parameter which is the ratio of the seawall freeboard to the local wave severity. This finding logically led to the development of three progressively more complex overtopping models. The models provide a relatively simple way to estimate overtopping rates and an objective way to evaluate the hydraulic performance of seawalls/revetments. Advantages and disadvantages of the models are discussed and their ability to predict overtopping rates is compared.

INTRODUCTION

Wave runup and overtopping are two of the most important factors influencing the design of coastal structures. Current methods to predict overtopping rates, such as given in the Shore Protection Manual (SPM, 1984), rely on a data base composed of laboratory tests using monochromatic waves. In addition, problems arise in using the SPM method because of uncertainty in choosing proper overtopping coefficients and treating wave runup as an independent variable. Studies have been conducted which indicate that the SPM method can, for some circumstances, under predict overtopping rates (Douglass, 1986) and for other circumstances greatly over predicts the rates (Gadd, et al. 1985). When these over estimates or underestimates of overtopping rates might be expected is unclear. Recent laboratory work using irregular waves has produced an alternative to the SPM method of calculating overtopping rates.

Data for 13 different seawall and seawall/revetment configurations has been collected and collated into 7 representative data sets. Examination of these data sets revealed that all had the common property that the overtopping rate could be expressed as an exponential function of a dimensionless freeboard parameter. This characteristic

¹Oceanographer, Coastal Engineering Research Center, U.S. Army Engineer Waterways Experiment Station, P.O. Box 631, Vicksburg, MS 39180

²Civil Engineer, Coastal Engineering Research Center, U.S. Army Engineer Waterways Experiment Station, P.O. Box 631, Vicksburg, MS 39180

held regardless of whether the overtopping rate was expressed as a dimensional or dimensionless variable. Similar findings have been reported by Owen (1982) and Jensen and Juhl (1987). This paper will develop three exponential overtopping models which represent a logical extension of the general relation. Each model has characteristics which are useful and the advantages and disadvantages of each model will be discussed. A criteria for comparing the models will be presented and their ability to predict overtopping rates will be compared.

DATA COLLECTION

Laboratory tests were conducted in the Coastal Engineering Research Center's (CERC) 45.73m long, 0.91m wide, and 0.91m deep wave tank and the 76.20m long, 3.35m wide, and 1.83m deep wave tank. All tests used irregular waves generated by computer controlled, hydraulically actuated, piston type wave boards.

Data sets were compiled from three separate CERC studies. One study tested three seawall/revetment configurations which have been proposed to protect the historic lighthouse at Cape Hatteras, North Carolina (Grace and Carver 1985). A second study tested a number of seawall/revetment configurations proposed to improve the performance of existing seawalls at Roughans Point, Massachusetts, (Ahrens, et al. 1986). The third study tested a seawall proposed to protect Virginia Beach, Virginia, (Heimbaugh, et al. 1988). Research funds were used to extend the range of conditions tested to allow the development of more general relationships.

Each test consisted of approximately 30 minutes of irregular wave generation during which wave conditions were measured using resistance type wave gages. Incident and reflected wave spectra were resolved using the method of Goda and Suzuki (1976). Water was allowed to pass over the seawalls and collected in a calibrated container. Elevations in the container were measured with a point gage before and after each test. Figure 1 shows simple profiles of each seawall/revetment configuration used to compile the seven data sets, and Table 1 summarizes test conditions for each data set. More detailed descriptions of test conditions and testing procedures can be found in references cited above.

METHOD OF ANALYSIS AND FINDINGS

One of the most important findings to date is the development of an effective dimensionless freeboard parameter, denoted F' . F' can consolidate all of the overtopping data for similar structure configurations into a single, well defined trend. F' is defined

$$F' = \frac{F}{\left(H_{mo}^2 L_p \right)^{1/3}} \quad (1)$$

where F , the freeboard, is the average vertical distance from the mean local water level to the crest of the seawall, H_{mo} is the energy based zero-moment wave height either measured near the structure (data sets 1 through 6) and assumed to be representative of H_{mo} at the toe of the seawall/revetment, or measured at the toe (data set 7). L_p is the Airy wave length calculated using the nominal T_p (data sets 1 through 6) and the water depth at the

Figure 1. Simple geometric profiles used in each data set

structure toe, d_s , or the measured T_p (data set 7), where T_p is the period of peak energy density of the wave spectrum. The nominal T_p used in data sets 1 through 6 was an assumed period based on the known peak period generated at the wave board and T_p for data set 7 was the measured peak period using a three gage Goda array.

The relative freeboard, F' , is the ratio of the freeboard to the severity of the local wave conditions. For energy based wave conditions the severity seems to be better characterized by variables containing L_D than by just H_{mo} (Ahrens 1987). The overtopping parameter F' is efficient since it contains in one term information about the water level, structure height, and wave conditions. During a test series on a seawall/revetment configuration, as wave conditions become more severe, a point is reached where details of the structure's geometry seem to have little influence on the overtopping rate. This point occurs when a combination of a high water level and large waves causes the structure to be virtually swamped or inundated by wave action. Inundation occurs when $F' < 0.3$.

Three exponential models have been found useful in estimating overtopping rates and evaluating the performance of seawalls and seawall/revetment configurations. The models in order of increasing complexity are:

$$\text{Model 1, } Q = Q_o \exp (C_1 F') \quad (2)$$

$$\text{Model 2, } Q' = Q'_o \exp (C_1 F') \quad (3)$$

$$\text{Model 3, } Q' = Q'_o \exp (C_1 F' + C_2 X_2) \quad (4)$$

where Q is the overtopping rate in cubic meters per second per meter length of seawall crest and Q' is the dimensionless overtopping rate given by

$$Q' = \frac{Q}{\sqrt{g H_{mo}^3}} \quad (5)$$

where g is the acceleration of gravity. Q_o is an overtopping coefficient having the same units as Q . Overtopping coefficients Q'_o , C_1 , and C_2 are dimensionless coefficients determined by regression analysis. The term " X_2 " in Model 3 can be any one of several dimensionless variables which improve the predictive ability of Model 3 over Model 2.

During regression analysis of the data a weight function was used to reflect the greater importance of tests which produced high overtopping rates. The weight function used is defined as

$$\text{weight function} = \text{Int} (Q \times 100) + 1 \quad (6)$$

where, Int, indicates that the quantity in parenthesis is a truncated integer and Q is the overtopping rate in English units, i.e. $\text{ft}^3/\text{ft-sec}$, converted to prototype values. Taking the logarithm of the models in order to linearize them and determine overtopping coefficients tends to decrease the relative influence of tests with high overtopping rates. In addition, tests with low rates have a higher percent error associated with measuring the overtopping volume. The weight function given by Equation 6 is an attempt to balance these undesirable effects on the regression process.

Each of the models has certain advantages and disadvantages which will be illustrated using data set 1 (Table 1) as an example. Figure 2 shows a detailed profile of the seawall configuration for data set 1. The seawall is basically a vertical wall without a fronting revetment and a small recurve at the crest (see Ahrens, et al. 1986

Figure 2. Data set 1 seawall configuration

for further details). Figures 3a through 3c compare predicted versus observed overtopping rates using Models 1 through 3 for predicted values, respectively. Figures 4a through 4c show the observed and predicted values of Q or Q' as a function of F' for Models 1 through 3, respectively. In Figure 4c a horizontal line indicates an overtopping rate of $0.05 \text{ m}^3 / \text{m-sec}$ which represents the approximate upper limit of overtopping for structure safety, Goda (1987). Figure 4c illustrates an advantage of Model 1, overtopping is given in dimensional units which can be directly related to potential flooding, levels of damage, or levels of danger, such as discussed by Fukuda et al. (1974) and tabulated in Owen (1982).

By intercomparing Figures 3a, 3b, and 3c, it can be seen that Model 3 is best at predicting Q . The same conclusion is reached using the correlation coefficients for data set 1 given in Table 2. This finding would be expected since Model 3 has the second variable, X_2 , which improves the prediction based on just F' . Table 2 shows that the secondary variable for data set 1 is F'/d_B . Considerable trial and error effort went into the selection of the secondary variable for each data set. In Table 2 the secondary variable which worked best with F' in predicting Q' is listed by data set. In four of the seven data sets the most important second independent variable to use with F' is the wave steepness parameter,

$$x_2 = \left(\frac{H_{mo}}{L_o} \right)^{1/2}$$

where,

$$L_o = \frac{g T^2}{2\pi}$$

The influence of steepness in predicting Q' indicates that surf conditions and their affect on potential runup are quite important to the overtopping process on some structures. For data sets 4 and 6 the influence of the rubble berm in front of the wall is important and the secondary variables reflect this fact. The secondary variables which improve the prediction of Q' for data sets 4 and 6 are W_B/L_p and H_{mo}/d_B respectively, where W_B is the width of the berm and d_B is the water depth over the berm. Review of the data and test conditions suggest that when the water depth over the berm is small the berm depth is quite important, e.g. data set 6, but a relatively modest

	3	1 -11.174 -10.664	Q_o' F^2 $(H_{mo}/L_o)^{1/2}$		0.948	

*NOTE Q_o in Model 1 is dimensional while Models 2 and 3 are dimensionless.

increase in water depth causes the width of the berm to be the more important characteristic, e.g. data set 4. In some instances it was not clear why one choice of a secondary variable was better than another choice. Since the secondary variables are partly dependent on the conditions tested the model 3 approach should not be regarded as producing an overly general formula.

In Table 2 a correlation coefficient is given for each model for each data set. This coefficient is the correlation between the predicted and observed dimensional overtopping rates. Using this correlation coefficient provides a fair way to compare the effectiveness of the three models. For some data sets Model 2 has a lower correlation coefficient than Model 1, which suggest that the method of normalizing Q was not optimum for that data set. In one case, data set 5, Model 1 even had a higher correlation coefficient than model 3. It is assumed that normalizing Q interfered with the surprisingly high correlation between Q and F' . Of course, it was necessary to normalize Q the same way for all data sets in order to make comparisons. Quite a few different ways to normalize Q were tried. Ideally it would be advantageous to normalize Q using wave condition variables H_{m0} , L_p , and T_p and use characteristics of the geometry of the seawall/revetment and water depth to formulate the dimensionless independent variables. Attempts to develop an effective overtopping prediction method based on separating wave and structure variables was unsuccessful. Experience from this study indicates that there does not seem to be a conspicuously superior way to normalize Q ; this finding is consistent with those of Jensen and Juhl (1987).

Inspection of Table 2 indicates that Model 3 does a substantially better job predicting overtopping rates for data sets 1, 4, 5, 6, and 7 than for data sets 2 and 3. Data sets 2 and 3 were the only ones with the correlation between predicted and observed overtopping rates less than 0.90. Data sets 2 and 3 were also the only data sets where tests of seawall/revetment configurations with slightly different geometries were lumped together. In all of the other data sets the wave heights, wave periods, and water depths were varied but there were no changes in the geometry of the structure. The conclusion is that small changes in geometry of a seawall/revetment configuration can have an important influence on the overtopping rate but is difficult to properly account for the change in a simple overtopping model. This finding is consistent with Owen (1980) who tabulates different overtopping coefficients for each different profile tested of embankment type seawalls, Jensen and Juhl (1987) who show different overtopping curves for each breakwater and sea dike tested, and Bradbury and Allsop (1988) who tabulate different overtopping coefficients for each breakwater crown wall configuration tested.

One of the useful characteristics of model 2 is that it can be easily used to generate a hydraulic inefficiency coefficient, A'_q , for a seawall/revetment configuration. A'_q is defined as the area under the curve, such as shown in Figure 4b, between $F' = 0.30$ and infinity. The lower limit of integration has been set at the approximate value of F' where wave inundation of the structure becomes the dominant mode of overtopping. Symbolically we have

$$A'_q = Q'_o \int_{0.30}^{\infty} \exp(C_1 F') dF' = -\frac{Q'_o}{C_1} \exp(0.30 C_1)$$

Values of A'_q are given in Table 2. Generally the ranking of the structures using A'_q seems logical with some small surprises. The stepped seawall with a moderate recurve, data set 7, seems to perform below expectations. When the data sets based on seawalls with recurved parapets are examined, data sets 4, 5, and 7, the vertical scale of the recurves for data sets 4 and 5 are larger in relation to the incident H_{mo} than the recurve for data set 7. It may be that the recurves used for data sets 3 and 4 are more effective than the one used for data set 7, partly because they represent a larger discontinuity to the runup flow, even though they are partly submerged at high water levels. Table 3 summarizes the relevant information on discontinuity effects for recurved parapets on seawalls for heavy overtopping conditions and long period waves. Ranking seawalls on the basis of A'_q values also indicates that the small curve at the crest of the wall tested for data set 1 is effective despite its small size.

Table 3. Discontinuity effects for recurved parapets on seawalls for heavy overtopping conditions, $F' = 0.30$, and long waves, $T_p = 3.0$ sec

Data Set	d_s for a High Water Level cm	Freeboard cm	Vertical Height of Recurved cm	H_{mo} for Heavy Overtop cm	Discontinuity/ H_{mo}
4	23.1	13.5	21.3	14.3	1.49
5	23.1	12.9	20.8	13.4	1.55
7	14.0	9.6	9.1	9.7	0.94

SUMMARY AND CONCLUSION

Results from an extensive series of laboratory tests of irregular wave overtopping of a number of seawall and seawall/revetment configurations are presented. Overtopping rates were found to be strongly dependent on a dimensionless freeboard parameter, F' , which is the ratio of the freeboard to a measure of the local wave severity, Equation 1. There is an approximately exponential relation between Q and F' which logically leads to the development of three progressively more complex overtopping models, Equations 2, 3, and 4. The primary purpose of the models is to predict overtopping rates but they are also useful for evaluating various strategies to reduce overtopping and ranking the hydraulic performance of the structures. Model 3 is the most complex and usually makes the best estimates of overtopping rates, however, no completely satisfactory approach has been developed which will provide a good generalized overtopping model for a variety of seawall and seawall/revetment configurations.

CHAPTER 60

Closed-Form Solutions for the Probability Density of Wave Height in the Surf Zone

William R. Dally¹, M.ASCE and Robert G. Dean², M.ASCE

Abstract

By invoking the assumption that in the surf zone, random waves behave as a collection of individual regular waves, two closed-form solutions for the probability density function of wave height on planar beaches are derived. The first uses shallow water linear theory for wave shoaling, assumes a uniform incipient condition, and prescribes breaking with a regular wave model that includes both bottom slope and wave steepness effects on the rate of decay. In the second model, the shallow water assumption is removed, and a distribution in wave period (incipient condition) is included. Preliminary results indicate that the models exhibit much of the behavior noted for random wave transformation reported in the literature, including bottom slope and wave steepness effects on the shape of the probability density function.

Introduction

The probability density function (pdf) for wave height in the surf zone is a subject of distinct import, as the transformation of random waves due to shoaling and breaking is the primary driving force in beach dynamics. Figure 1 contains histograms of wave height, H , non-dimensionalized by the local average height, \bar{H} , observed at different times at the same location in the inner surf zone during the DUCK '85 field experiment, as reported in Ebersole and Hughes (1987). Note that the general shape of the pdf varies significantly, depending on incident wave characteristics and tide elevation. It is stressed that the pdf does not appear to have a typical shape, at least one that is easily recognized.

Most previous efforts to model the transformation of random waves along a beach transect, e.g. Collins (1970), Kuo and Kuo (1975), Goda (1975), Battjes and Janssen (1978), and Thornton and Guza (1983), start with the Rayleigh distribution outside the surf zone, and rely on the assumption that the height of an individual wave is directly proportional to the local water depth in order to represent energy dissipation due to breaking; i.e.,

¹Florida Institute of Technology, Oceanography and Ocean Engineering, 150 W. University Blvd., Melbourne, Florida 32901, U.S.A.

²Coastal and Oceanographic Engineering Department, 336 Weil Hall, University of Florida, Gainesville, Florida 32611, U.S.A.

Figure 1 - Sample histograms of dimensionless wave height (H/\bar{H}) observed at the same location (pole#6) during DUCK'85 field experiment. Data reported in Ebersole and Hughes (1987). Waves were identified using the zero-down-cross technique.

$$H = \gamma h \quad (1)$$

where h is water depth and γ is a coefficient whose behavior must be parameterized empirically. As described by Collins (1970), this results in a pdf shape that at its upper limit contains a spike of finite area - a shape not supported by data. Kuo and Kuo (1975), Goda (1975), and Thornton and Guza (1983) remove this behavior with various ad hoc treatments that require additional empirical fitting. However, adopting a single basic shape for the pdf a priori results in only limited agreement to the wide variety of histograms found in reliable field data, as evidenced by Figure 1.

Mase and Iwagaki (1982) and Dally and Dean (1986) approach the problem in basically the same manner as Collins (1970), but employ models more realistic than (1) for describing the decay of individual waves. Because the pdf is allowed to transform "naturally", i.e. no typical shape is adopted a priori, better agreement with observed histograms is attained. While γ in (1) has been parameterized in terms of bottom slope and deepwater wave steepness, the expressions for decay of individual waves adopted by Mase and Iwagaki (1982) and Dally and Dean (1986) include the effect of bottom slope and wave steepness on the shape of the decay profile. That is, they model the observational fact that the gradient in wave height is rarely uniform across a beach of uniform slope (see Horikawa and Kuo, 1966). In result, for random waves the observed dependence of the transformation of both the pdf and statistically representative waves (e.g. H_{rms} and $H_{1/3}$) on beach slope and mean wave steepness, as discussed in Thornton, Wu and Guza (1984) and Sallenger and Holman (1985), is more faithfully represented. Both of these models require numerical solution which, although suitable and practical for engineering application, does not facilitate study of the general behavior of the pdf. The purpose of this paper is to present two closed-form solutions which will hopefully serve to better edify the problem of random wave transformation, and provide a theoretical foundation for future work in stochastic modeling of surf zone dynamics and design of engineering projects.

Closed-Form Solution #1

The first closed form solution is the subject of an upcoming paper by one of the authors (Dally, 1988), in which its derivation, analysis of the behavior of the solution, and comparison to field data are described in detail. Consequently, only a brief overview is presented below.

As an initial condition, we adopt the Rayleigh pdf for wave height, truncate it at some realistically large wave height, and assume no waves are breaking, i.e.,

$$\begin{aligned} \text{pdf}(H_1) &= \frac{2H_1}{H_{rms1}} \exp \left[-\frac{H_1^2}{H_{rms1}^2} \right] & H_1 \leq \gamma h_1 \\ &= 0 & H_1 > \gamma h_1 \end{aligned} \quad (2)$$

where the subscript "1" denotes initial conditions. Set-up is not included, and in this first solution γ is assumed constant.

The area lost above the truncation point, Ω_t , is equal to

$$\Omega_t = \int_{\gamma h_1}^{\infty} \text{pdf}(H_1) dH_1 = \exp -(\gamma h_1 / H_{\text{rms}1})^2 \quad (3)$$

which shows that starting in water much deeper than the root mean square wave height will make Ω_t negligible. Otherwise, the pdf should be normalized by dividing by the quantity $(1 - \Omega_t)$. The random variable H_1 is now transformed to local wave height H due to either shoaling or breaking, as a function of the local water depth, h .

Shoaling waves - It is now assumed that linear shallow water wave theory is valid, so that from Green's Law

$$H_1 = H (h/h_1)^{1/4} \quad (4)$$

Calculating the Jacobian and performing a standard transformation of random variable yields

$$\text{pdf}(H)_{\text{sh}} = \frac{2H}{H_{\text{rms}1}} (h/h_1)^{1/2} \exp\left[-\frac{H^2}{H_{\text{rms}1}^2} (h/h_1)^{1/2}\right] \quad (5)$$

where subscript "sh" denotes the pdf for shoaling waves. This distribution, which still has a Rayleigh shape, must be truncated at the largest wave height that can occur at the local water depth, i.e., $H \leq \gamma h$. If the random variable is non-dimensionalized by the initial root mean square height, $H_{\text{rms}1}$, we obtain

$$\text{pdf}(A)_{\text{sh}} = 2A \hat{h}^{1/2} \exp(-A^2 \hat{h}^{1/2}) \quad A \leq A_{\text{max}} \quad (6)$$

where $A = H/H_{\text{rms}1}$, $A_{\text{max}} = \gamma h/H_{\text{rms}1}$, and $\hat{h} = h/h_1$.

Breaking waves - The probability density function of wave height for broken waves is derived in a similar manner, but in two steps. The random variable H_1 is first transformed to h_b , the water depth at which incipient breaking is attained, by applying Green's Law

$$H_1 = \gamma h_b^{5/4} h_1^{-1/4} \quad (7)$$

To transform from h_b to H , we utilize the analytical solution to the model of Dally, Dean, and Dalrymple (1985) for regular waves breaking on a planar beach (neglecting set-up). When inverted this solution becomes

$$h_b = \left[\frac{H^2 + \alpha h^2}{(\gamma^2 + \alpha) h^{(K/m-1/2)}} \right]^{1/(5/2-K/m)} \quad (8)$$

where

$$\alpha = \frac{(K/m)\Gamma^2}{(5/2 - K/m)} \quad (9)$$

m is beach slope, K is the decay coefficient (~ 0.17), and Γ the stable wave factor (~ 0.50). Performing the transformation and again nondimensionalizing by H_{rms1}, the portion of the pdf due to broken waves is

$$\text{pdf}(A)_{br} = \frac{5 A \hat{h}^{(1/2-K/m)} B^{K/m}}{|(5/2 - K/m)|(\gamma^2 + \alpha)} \exp\left[-\left(\frac{\gamma h_1}{H_{rms1}}\right)^2 B^{5/2}\right]; A_{min} \leq A \leq A_{max} \tag{10}$$

$$\text{where } B = \left[\frac{\left(\frac{H_{rms1}}{h_1}\right)^2 A^2 + \alpha \hat{h}^2}{(\gamma^2 + \alpha) \hat{h}^{(K/m-1/2)}} \right]^{1/(5/2-K/m)} \tag{11}$$

This distribution must be truncated not only at the upper limit A_{max} = γh/H_{rms1}, but also at the lower bound given by the breaking wave height that corresponds to the largest wave of the original pdf(H₁). By applying the original solution for regular waves we find

$$A_{min} = \left[\hat{h}^{(K/m-1/2)} (\gamma^2 + \alpha) - \alpha \hat{h}^2 \right]^{1/2} (h_1/H_{rms1}) \tag{12}$$

If γ and m are such that the decay profiles are convex, A_{max} and A_{min} switch.

The expressions (6) and (10) are plotted in Figure 2a for a beach slope m = 1/80 and γ = 0.78, in Figure 2b for m = 1/50 and γ = 1.0, and in Figure 2c for m = 1/20 and γ = 1.2. Note that for the mild beach slope, as one moves into the surf zone, area is taken from the shoaling pdf and "piled up" at the lower breaking wave heights of the breaking pdf and not the upper limiting wave height, as is the case for the steep beach and was assumed by Collins (1970). This is in at least qualitative agreement with field data, as demonstrated by the observations of Ebersole and Hughes (1987). The apparent discontinuity in the model pdf at the lower limit of the breaking portion also appears in this data set, as is shown in Figure 1. However, the model does tend to overpredict the amount of this abrupt jump in the pdf; plus, observed histograms display a slightly more gradual decline over the upper range of wave height, as opposed to the truncation assumed by the model. These characteristics in the model result from neglecting the mechanisms present in nature which smooth the pdf, such as surf beat and a varying height to depth ratio at incipient breaking. The numerical solution of Dally and Dean (1986) and Dally (1987) includes both of these effects. In the next closed form solution to be presented however, it is only practicable to address the variation in the incipient breaker condition.

Closed-Form Solution #2

To improve upon the first solution, in the following the shallow water assumption is removed and the incipient condition varies according to a general form for available empirical expressions, e.g. Moore (1982), which is a hybrid of Weggel (1972) and Komar and Gaughan (1972):

$$\gamma = b(m) - a(m) \left[\frac{0.36}{(2\pi)^{4/5}} \left(\frac{H_o}{L_o}\right)^{4/5} \right] \tag{13}$$

Figure 2 - Transformation of the pdf of wave height across the surf zone according to solution #1, (6) and (10).
 a) beach slope $m=1/80$, incident condition $\gamma = 0.78$; b) $m=1/50, \gamma = 1.0$; c) $m=1/20, \gamma = 1.2$.

where

$$a(m) \approx 43.8(1.0 - e^{-19 m}) \quad (14)$$

$$b(m) \approx 1.56/(1.0 + e^{-19.5m}) \quad (15)$$

L is wave length and the subscript "o" denotes deepwater conditions.

These improvements require knowledge of the distribution of wave period, and so we will conduct a series of transformations of a joint pdf in two random variables. In the final step the second random variable is integrated out to obtain the marginal pdf of shoaling and breaking wave heights. It is noted that the formulation presented below is identical in basis to one solved numerically in Dally and Dean (1986).

The initial condition is taken to be the joint probability density function for wave height and period in deep water as derived by Longuet-Higgins (1983), which is

$$\text{pdf}(R_o, \tau) = C_1 \frac{R_o^2}{\tau^2} \exp\left\{-R_o^2\left[1 + \frac{1}{v^2}\left(1 - \frac{1}{\tau}\right)^2\right]\right\} \quad (16)$$

$$\text{where} \quad R_o = H_o/H_{rmso} = H_o/\sqrt{8a_0} \quad (17)$$

$$\text{and} \quad \tau = T/\bar{T} = T \frac{a_1}{2\pi a_0} \quad (18)$$

T and \bar{T} are wave period and average wave period, a_0 is the area under the measured spectral density function in deep water, and a_1 is the first moment of this area. The coefficient C_1 is given by

$$C_1 = \frac{4}{\sqrt{\pi} v} \left[1 + (1 + v^2)^{-1/2}\right]^{-1} \quad (19)$$

and v is the band-width parameter determined by the first three moments of the spectrum

$$v = \left[\frac{a_0 a_2}{(a_1)^2} - 1\right]^{1/2} \quad (20)$$

Shoaling waves - Although the transformation could be performed in one step, for better tractability, the pdf for shoaling waves will be developed in two steps. The first is to transform τ to deepwater relative depth, D_o

$$D_o = k_o h = \frac{(2\pi)^2}{gT^2} h \quad (21)$$

and so

$$\tau = \frac{2\pi}{T} \left(\frac{h}{gD_o} \right)^{1/2} \quad (22)$$

and the joint pdf is transformed to

$$\text{pdf}(R_o, D_o) = \frac{C_1}{2} R_o^2 \frac{T}{2\pi} \left(\frac{g}{hD_o} \right)^{1/2} \exp(-R_o^2 \left\{ 1 + \frac{1}{\sqrt{2}} \left[1 - \frac{T}{2\pi} \left(\frac{gD_o}{h} \right)^{1/2} \right]^2 \right\}) \quad (23)$$

The second step is to transform the deepwater wave height to the local shoaling wave height. By applying conservation of energy flux and invoking linear wave theory yields

$$R_o^2 \frac{gT}{4\pi} = R^2 \left[\frac{g \tanh kh + gkh(1 - \tanh^2 kh)}{2(gk \tanh kh)^{1/2}} \right] \quad (24)$$

From the dispersion relation and adopting the notation $D = kh$, (24) reduces to

$$R_o^2 = R^2 \left[\frac{D_o + D^2 - D_o^2}{D} \right] \quad (25)$$

An approximate solution to the dispersion relation given by Hunt (1979) is

$$D^2 = D_o^2 + \frac{D_o}{1 + \sum_{n=1}^{\infty} d_n D_o^n} \quad (26)$$

in the present notation (d_n are provided constants), and (25) can now be expressed explicitly in terms of D_o

$$R_o = R \left\{ \frac{1 + 1/(1 + \Sigma)}{[1 + 1/D_o(1 + \Sigma)]^{1/2}} \right\}^{1/2} \quad (27)$$

where Σ denotes the summation in (26). Finally, the joint probability density function of shoaling wave height and deepwater relative depth is produced

$$\text{pdf}(R, D_o)_{sh} = \frac{C_1}{2} \bar{D}_o^{-1/2} D_o^{-1/2} \left\{ \right\}^{3/2} R^2 \exp(-R^2 \left\{ \right\} \left[1 + \frac{1}{\sqrt{2}} \left[1 - \left(\frac{D_o}{\bar{D}_o} \right)^{1/2} \right]^2 \right\}) \quad (28)$$

in which $\left\{ \right\}$ denotes the expression within the braces of (27) and

$$\bar{D}_o = \bar{k}_o h = \frac{2\pi}{L_o} h = 2\pi \frac{H_{rmso}}{L_o} \frac{h}{H_{rmso}} = 2\pi \bar{S}_o \hat{h} \quad (29)$$

\bar{S}_o is mean deepwater wave steepness and \hat{h} is dimensionless water depth.

The marginal pdf for dimensionless shoaling wave height is found by integrating between proper limits (numerically) with respect to deep-water relative depth D_o . These limits are defined by the incipient breaking condition, which is a function of deepwater steepness and bottom slope. This function can be expressed in a general form which encompasses most of the empirical relationships for γ available in the literature:

$$S_o = H_o/L_o = \frac{D_o R_o}{2\pi h} = [F(m, \gamma)]^p \tag{30}$$

As an example, for γ given by (13)

$$F = \left[\frac{b(m) - \gamma (2\pi)^{4/5}}{a(m)} \right] \tag{31}$$

and

$$p = 5/4 \tag{32}$$

The essence of the problem at hand is, given the local water depth and choosing a wave height of interest, what is the deepwater relative depth of the single wave that is at incipient breaking, if such a wave exists. If it does exist, all waves of that height but with smaller relative depth are still shoaling, while all waves of that height but greater relative depth are already breaking. Thus to determine the marginal pdf of shoaling wave height, the joint pdf(R, D_o)_{sh} is integrated according to

$$mpdf(R)_{sh} = \int_0^{D_{oI}} pdf(R, D_o)_{sh} dD_o \tag{33}$$

where D_{oI} is the deepwater relative depth of the wave with height R at incipient breaking. D_{oI} must be calculated numerically as is described in Dally (1987).

Breaking waves - Four steps will be required to derive the pdf of wave height due to breaking, represented conceptually by

$$\begin{aligned} pdf(H_o, T) &\Rightarrow pdf\left(H_o, \frac{H_o}{L_o}\right) \Rightarrow pdf(H_o, \gamma) \Rightarrow pdf(h_b, \gamma) \\ &\Rightarrow pdf(H, \gamma)_{br} ; mpdf(H)_{br} = \int_{\gamma_1}^{\gamma_2} pdf(H, \gamma)_{br} d\gamma \end{aligned} \tag{34}$$

Again starting with (16) and applying

$$\tau = \left(\frac{R_o}{S_o} \frac{H_{rmso}}{L_o}\right)^{1/2} = \left(\frac{R_o}{S_o} \bar{S}_o\right)^{1/2} \tag{35}$$

we obtain

$$\text{pdf}(R_o, S_o) = \frac{C_1}{2} \frac{R_o^{3/2}}{S_o^{1/2}} (\bar{S}_o)^{-1/2} \exp(-R_o^2 \{1 + \frac{1}{\nu^2} [1 - (\frac{R_o}{\bar{S}_o})^{-1/2}]^2\}) \quad (36)$$

In the second step, (30) is employed so that

$$\text{pdf}(R_o, \gamma) = \frac{C_1}{2} (\bar{S}_o)^{-1/2} R_o^{3/2} p_F^{(P/2-1)} |\partial F / \partial \gamma| \cdot \exp(-R_o^2 \{1 + \frac{1}{\nu^2} [1 - (\frac{R_o}{F^P} \bar{S}_o)^{-1/2}]^2\}) \quad (37)$$

We now apply conservation of energy flux between the deepwater wave and the same wave at incipient breaking (which is in shallow water)

$$\frac{R_o^2 L_o^{1/2} \sqrt{g}}{2\sqrt{2\pi}} = R_b^2 \sqrt{gh_b} = \frac{\gamma^2 h_b^2}{H_{rmso}^2} \sqrt{gh_b} \quad (38)$$

Rearranging and applying (30) yields

$$R_o = \hat{h}_b (8\pi)^{1/5} \gamma^{4/5} [F(m, \gamma)]^{P/5} \quad (39)$$

where $\hat{h}_b = h_b / H_{rmso}$, and the joint pdf of \hat{h}_b and γ is determined

$$\text{pdf}(\hat{h}_b, \gamma) = \frac{C_1}{2} (\bar{S}_o)^{-1/2} (8\pi)^{1/2} \gamma^2 p_F^{(P-1)} |\partial F / \partial \gamma| \hat{h}_b^{3/2} \cdot \exp(-\hat{h}_b^2 (8\pi)^{2/5} \gamma^{8/5} F^{2P/5} \{1 + \frac{1}{\nu^2} [1 - (\frac{\hat{h}_b (8\pi)^{1/5} \gamma^{4/5} \bar{S}_o}{F^{4P/5}})^{-1/2}]^2\}) \quad (40)$$

The final transformation again utilizes the inverted analytic solution for wave decay on planar beaches (8) which in the present dimensionless notation is

$$\hat{h}_b = \left[\frac{R^2 + \alpha \hat{h}^2}{\hat{h}^{(K/m-1/2)} (\gamma^2 + \alpha)} \right]^{1/5} \frac{1}{5/2 - K/m} \quad (41)$$

Finally, the joint pdf of R and γ for breaking waves is

$$\begin{aligned}
 \text{pdf}(R, \gamma)_{br} &= \frac{C_1}{2} (\bar{S}_o)^{-1/2} (8\pi)^{1/2} \gamma^2_p F^{(p-1)} \left| \frac{\partial F}{\partial \gamma} \right| \left[\left(\frac{K/m}{5/2 - K/m} \right) \right. \\
 &\quad \cdot \frac{1}{|5/2 - K/m|} \frac{2R}{h^{(K/m-1/2)} (\gamma^2 + \alpha)} \\
 &\quad \cdot \exp(-[\left(\frac{2}{5/2 - K/m} \right) (8\pi)^{2/5} \gamma^{8/5} F^{2p/5} \\
 &\quad \left. \left\{ 1 + \frac{1}{\sqrt{2}} \left[1 - \left(\frac{1}{F^{4p/5}} \frac{1}{[\left(\frac{1}{5/2 - K/m} (8\pi)^{1/5} \gamma^{4/5} \bar{S}_o \right)^{-1/2} \right]^2} \right) \right] \right\} \right] \Bigg)
 \end{aligned}
 \tag{42}$$

where [] denotes the quantity in the brackets of (41). The region of integration for γ and the numerical procedure followed are described in detail in Dally (1987). Example results for the marginal pdf(R) are displayed in Figures 3a, 3b, and 4. Note that in Figure 3 the closed form solution for breaking on the 1/20 slope has been smoothed, and that the discontinuity at the upper bound of the pdf has been eliminated. For mild beach slopes, the anomaly in the lower range of values for breaking waves displayed by the first model (Figure 2a) still exists as shown in Figure 4 for a beach slope of 1/80.

To test the sensitivity of the model to the expression chosen to dictate incipient breaking, that given by Singamsetti and Wind (1980),

$$\gamma = 0.568 m^{0.107} \left(\frac{H_o}{L} \right)^{-0.237}
 \tag{43}$$

is also applied and results for the same conditions as Figure 3a are displayed in Figure 5. This breaker criterion allows more range in values of γ than (13), perhaps more than is actually found in nature and in fact has no upper limit. This is responsible for the broad and flat shape of the pdf for broken waves, and the upper tail of the pdf for shoaling waves as compared to Figure 3a.

Discussion and Conclusions

Due to space limitations, direct comparison of the models to observed histograms cannot be presented here. However, in Dally (1988) solution #1 is compared to the field data of Ebersole and Hughes (1987), while Dally and Dean (1986) and Dally (1987), applying to complex topography the same formulation as developed for solution #2, compared direct numerical solutions to the field data of Hotta and Mizuguchi (1980, 1986). The model comparisons are quite reasonable, and faithfully represent major features of the shape of observed histograms as the surf zone is traversed. As hoped, allowing for a variation in γ in solution #2 does improve agreement, especially across the range of higher wave heights. As previously noted, the models do tend to overpredict measured values near the mean wave height for mild beach slopes - behavior

Figure 3 - Transformation of the pdf of wave height across the surf zone according to solution #2, (28) and (42) for beach slope $m=1/20$. a) mean deepwater steepness $S_0=0.02$; b) $S_0=0.005$.

Figure 5 - Transformation of the pdf of wave height across the surf zone according to solution #2, (28) and (42), for beech slope $m=1/20$. Incipient condition of Singamsetti and Wind (1980), (43), utilized.

Figure 4 - Transformation of the pdf of wave height across the surf zone according to solution #2, (28) and (42), for beech slope $m=1/80$.

most likely due to neglecting surf beat. Comparison of the transformation of statistically representative waves H_{rms} , $H_{1/3}$ and $H_{1/10}$ as predicted by the second formulation are also in good agreement with data from Hotta and Mizuguchi (1980, 1986).

The degree to which the closed-form solutions represent random wave transformation is directly attributed to the ability of the regular wave model (8) to predict breaking of individual waves. It is stressed that favorable results have been obtained without altering the original calibration of the regular wave model. Because the effect of beach slope and wave steepness on wave height decay appears to be well represented in the regular wave model (see Dally et al., 1985), the ability of the random wave models to predict the effect of these parameters on the behavior of the pdf is significantly enhanced. This also holds true for the behavior of statistically representative waves calculated using solution #1 as pursued in Dally (1988). The closed-form nature of the solutions intrinsically identifies the dimensionless parameters governing the problem, and allows the predicted response to them to be more easily examined. For example, intercomparison of Figures 2a, b and c clearly shows the effect of beach slope, while 4a and b display the effects of mean wave steepness, with all other parameters held constant. Although in solution #2 numerical quadrature is required to determine the marginal pdf, (28) and (42) are in closed form, and could be utilized as a starting point for stochastic treatment of other surf zone problems.

Numerical studies reported in Dally and Dean (1986) and Dally (1987) indicate that comparisons of the model to field data are improved when the formulation includes 1) non-linear effects in wave shoaling, and 2) the effects of the fluctuating mean water level and oscillatory current associated with surf beat. However, a closed-form solution that includes these effects has thus far been elusive.

CHAPTER 61

DESIGN WAVES AND THEIR PROBABILITY DENSITY FUNCTIONS

by

J Rossouw

Abstract

Design wave heights were estimated from measured data using a virtually continuous data set consisting of 8 years of waverider data. Evidence is given which shows that waveriders tend to malfunction during storms. Special care was taken to select independent and identically distributed samples from the data before fitting a number of probability distributions to the selected wave heights. Bootstrap techniques were used to select the models that give the best fit to the data as well as to determine the confidence bands for the predicted design wave heights. It is shown that once the model for the long term distribution of wave height is chosen, relatively narrow confidence bands can be obtained for the most probable value of up to the 100 year return period wave if maximum use is made of the available data. Uncertainty about the selection of the model and the representativeness of the measurements however reduces the usefulness of these confidence bands. A plea is also made in the paper to stop using the concept of a wave with a certain recurrence interval but rather to specify a wave with a given risk of being exceeded within the design life of the structure.

1. The Data Set

Data obtained from the four sites shown in Figure 1 were used to compile a data set which gave a 90 per cent coverage over an 8 year period. These four sites from Cape Town in the West to Port Elizabeth in the East showed remarkable similarity in simultaneously recorded wave heights over distances as much as 700 km apart. An example of simultaneously recorded wave heights at stations 2 and 3 is shown in Figure 2. Similar examples were also shown in Rossouw et al (1982). The reason for the similarity in wave height over such large areas is due to the large size of the weather systems responsible for the higher wave events. A typical example of such a weather system is shown in Figure 3. Large spatial

Senior Lecturer, Dept of Civil Engineering, University of Stellenbosch, Republic of South Africa

FIGURE 1: RECORDING SITES

FIGURE 2: COMPARISON IN H_{mo} BETWEEN CAPE TOWN AND MOSSEL BAY

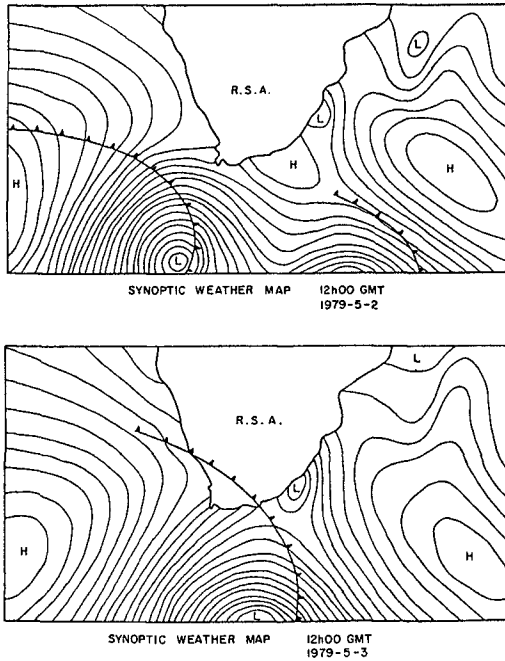

FIGURE 3: PASSAGE OF A COLD FRONT CAUSING HIGH WAVES ALONG THE RSA SOUTHERN COAST (ROSSOUW (1982))

variation in wave heights is not to be expected within such a weather system. These weather systems regularly move from West to East past the South African south coast and generates high waves at the four recording sites shown in Figure 1.

The data set was compiled by using the measurements at site 1 as basis and by filling gaps in this data set with data from stations 2, 3 and 4 in that order of preference. In this process it was noted that the waverider has a tendency to malfunction during the peak of the storms. Examples of this is shown in Figure 4. After filling the gaps a careful study was made of the weather maps during the periods where no records were available from any of the four stations, to ensure that no major storms were omitted from the data set.

2. Sampling from the data set

The basic data set consisted of 10 537 values of H_{mo} recorded at 6 hourly intervals. To make the maximum use of this data set it is important to obtain the maximum number of samples from the data set which will be independant and identically distributed.

FIGURE 4: TWO EXAMPLES WHERE WAYERIDER MALFUNCTIONED DURING PEAK OF STORM

2.1 Independence of the data

To test for independence between the recorded H_{mo} values, the serie-correlation coefficient were calculated using a lag of 6h, 12h, 18h, etc. The results are summarized in the Table 1 below:

TABLE 1: SERIE-CORRELATION COEFFICIENT AS FUNCTION OF LAG

LAG (HRS)	6	12	18	24	30	36	42	48	54	60	90	120
CORR COEFF	0,85	,71	,58	,46	,35	,27	,21	,16	,13	,093	,026	,008

The 6 hourly H_{mo} values are highly correlated with a serie-correlation coefficient of 0,85. The serie-correlation coefficient gradually reduces with increasing lag and only becomes smaller than 0,1 with a lag of 60 hours. To ensure that independent values of H_{mo} are selected it will therefore be necessary to ensure that not more than one sample is taken in each 60 hour period. When studying the recorded H_{mo} values, difficulty was experienced in selecting an independent event for each 60 hour period. This is illustrated in Figure 5 where the wave heights recorded during the passage of a series of cold fronts at roughly 5 day intervals are shown.

FIGURE 5: SELECTION OF MAXIMUM H_{mo} PER WEEK

It was therefore decided to rather base the selection of independent H_{mo} values on an event basis. The maximum H_{mo} recorded in each week of the recording period was therefore selected as a basis for the fitting of probability distributions and care was taken to ensure that the same event did not feature in successive weeks.

2.2 Identical distribution of the data

In an effort to obtain identically distributed samples, the months which shows similarity in recorded height were grouped together. In the Table 2 below the mean and standard deviation of the maximum weekly H_{mo} values are given.

TABLE 2: MEAN AND STANDARD DEVIATION OF MAX WEEKLY H_{mo} PER MONTH

	MAY	JUNE	JULY	AUG	SEPT	OCT	NOV	DEC	JAN	FEBR	MARCH	APRIL	YEAR
NUMBER OF WEEKS	31	28	29	30	31	28	29	31	32	29	30	31	359
MEAN	4,726	4,864	4,897	4,920	5,087	4,629	4,003	4,019	3,919	3,745	4,090	4,158	4,418
STANDARD DEVIATION	1,630	1,237	0,898	0,995	1,210	1,191	0,825	1,171	0,787	1,031	1,132	0,913	1,198

The mean values for the winter months May to September are fairly constant around 4,9 m whereas the mean for the summer months November to April are also nearly constant around 4,0 m. The standard deviations show no clear pattern with high values in the months where extreme storms occurred (i e May) and low values in the months that were free of such storms (i e January). For the purposes of selecting identically distributed data, the stormy months May to September were grouped together. The 149 weekly maximum values of H_{mo} obtained during these months were therefore used to represent the best estimate of independent and identically distributed samples.

2.3 Influence of sampling method on the predicted design wave heights

The influence of the sampling method on the predicted design wave heights were studied by calculating the most probable value of the 10 and 100 year wave according to the Extreme 1 distribution using the method of moments to fit the data. The sampling method used varied from using all 6 hour records for all months (10 537 records) to only using the maximum H_{mo} recorded in each year (8 records). The results are summarized below:

TABLE 3: EXTREME 1 DISTRIBUTION - COMPARISON OF SAMPLING METHODS

3.1 DATA FROM ALL MONTHS

Sampling method	N	H ₁₀	H ₁₀₀
All data	10 357	9,80	11,63
Max H _{mo} per week	359	9,73	11,88
Max H _{mo} per month	96	9,52	11,68
Max H _{mo} per year	8	9,53	11,88

3.2 DATA FROM STORMY MONTHS

Sampling method	N	H ₁₀	H ₁₀₀
All data	4 463	9,92	11,91
Max H _{mo} per week	149	9,50	11,72
Max H _{mo} per month	40	9,29	11,46
Max H _{mo} per year	8	9,53	11,88

As can be seen from the above table, the predicted design waves are very insensitive to the method of sampling with the most probable 10 year H_{mo} varying from 9,3 m tot 9,9 m and the 100 year H_{mo} from 11,3 m to 11,9 m. Neither the dependence of the data when using all the data, nor the non-identical distribution of the data when the calmer summer months are included, seem to seriously influence the result.

According to Wallis (1988) correlation between data should not alter the expected values but will influence the uncertainty of the estimates as measured by the confidence limits or r m s errors. In the example above however it should be considered fortuitous that such similarity in results were obtained when varying the number of samples from 8 to 10 537.

The fact that inclusion of the data from the calmer summer months in the data set did not seriously influence the result is not surprising due to the small difference in wave height between the summer and winter and the fact that the winter storms will dominate in the total data set.

3. Model selection

The procedure that is most often followed for selecting an appropriate model for the long term distribution of wave height is to fit the data to a number of these models and to select the model which fits the data best according to some goodness of fit criteria. This procedure have led many engineers and researchers to develop a preference for a particular model. In an effort to obtain a better fit of the model to the data, the number of parameters used in the model are often also increased.

The method of model selection described above has been severely criticized by a number of researchers such as Wallis (1988) and Linhart and Zucchini (1986). Authors such as Wallis (1988) have found that if they generate data according to a particular distribution and then use the above procedure of model selection, they frequently select a different distribution than the one used for the generation of the data. He illustrates for instance that by using 4 of the most popular models for the long term distribution of flood intensity and generate data according to one of these distributions, the correct distribution will be chosen less than 50 per cent of the time if 100 data points are used.

An approach to improve model selection is suggested by Linhart and Zucchini (1986). They propose the use of bootstrap sampling [Efron (1982)] whereby the models are not only fitted to the original data set but also to data obtained from resampling the original data set. Here it is important to have independent and identically distributed samples. The process of model selection proposed by them are as follows:

- (i) Select a number of likely models (Weibul, Extreme I, Log-normal, etc).
- (ii) Select a goodness of fit criteria - say Kolmogoroff discrepancy.
- (iii) Select a random sample of size n (with replacement) from the original observations to obtain a bootstrap sample.
- (iv) Calculate the parameters of the models selected in (i) above using the method of maximum likelihood.
- (v) Calculate the maximum discrepancy for each distribution.
- (vi) Repeat steps (iii) to (v) a large number of times (say 100) and keep track of the discrepancies.
- (vii) The model which gives the lowest average discrepancy over the 100 repetitions is chosen as the most appropriate.

This bootstrap sampling technique was applied to the 149 weekly maximum H_{mo} values recorded during the stormy months. Six probability distributions were considered i e the Gamma, Normal, Log-normal, Exponential, Weibul, and Extreme I distributions. The Kolmogoroff discrepancy was used as goodness of fit criteria and the method of maximum likelihood for parameter estimation. The results are summarized in the Table below showing the percentage of the time that the various models were selected, the average discrepancy for each model and the most probable value of the 100 year wave (H_{100}) for each model

TABLE 4: BOOTSTRAP SELECTION OF MODELS

Model	% Selected	Ave discrepancy	H_{100} (m)
Log-normal	54	0,066	10,7
Gamma	28	0,071	9,9
Extreme I	12	0,074	12,3
Normal	6	0,096	8,9

The result of this bootstrap method clearly illustrates the dilemma we face in model selection. The goodness of fit criteria chosen indicate that the first three models listed above all fit the bulk of the data reasonably well. The upper tail of these models do however differ significantly which result in large differences when these distribution are extrapolated to obtain design values. Emphasis on the upper tail of the distribution can be incorporated in the goodness of fit criteria but a sound statistical criteria whereby the degree of emphasis could be decided, is not available.

4. Confidence limits

Two types of uncertainties pertaining to the prediction of the extreme values of significant wave height lend themselves to statistical analysis i e:

- (i) If the long term distribution of wave height is perfectly known such as would be the case if we had an infinitely long and perfect wave record, there is still uncertainty about the largest wave that will occur within the next N years.
- (ii) If we are sure about the model that describes the long term distribution of wave heights, but we have to estimate the parameters of this distribution from a limited wave record, we are uncertain about the values of these parameters.

Other uncertainties which cannot so readily be addressed in statistical terms include:

- (iii) Decisions about the most appropriate model to describe the long term distribution of wave height.
- (iv) Whether the data recorded over a number of years can be considered representative of the long term distribution of the wave height.

Case (i)

This case can best be illustrated by means of an example. Let us assume that we have an infinitely long wave record and the maximum H_{mo} recorded during each year of the record follows an Extreme I distribution as follows:

$$H_{mo}(p) = 8,09 - 0,85 \ln(-\ln p) \dots\dots\dots (1)$$

where $p = 1 - \frac{1}{T}$ with T the return period in years.

The most probable 100 year wave, i e the wave that will occur on average once in a 100 years, is then given for

$$p = 1 - \frac{1}{100} = 0,99 \text{ by}$$

$$H_{mo}(0,99) = H_{mo_{100 \text{ years}}} = 12,0 \text{ m}$$

If the infinitely long record is broken into 100 year intervals, the highest H_{mo} in each 100 years will obviously not be the same but follow a distribution as shown in Figure 6.

FIGURE 6: DISTRIBUTION OF $H_{mo_{100 \text{ years}}}$

The general expression relating the wave height with a given risk (r) of being exceeded during T years to probability (P) is given by

$$p_T^r = (1-r)^{1/T} \dots\dots\dots (2)$$

If a designer therefore is designing a structure with a design life of say 30 years and he is only willing to take a 10 per cent risk of that wave height being exceeded during the 30 years, he must in our example substitute

$$p_T^r = (1 - 0,1)^{1/30} = 0,9965 \text{ in equation 1 to obtain:}$$

$$(H_{mo}^0)^{0.1} = 8,09 - 0,85 \ln(-\ln ,9965) = 12,9 \text{ m}$$

The reason for labouring this well known concept even to a learned audience such as the attendees of an ICCE, is that the author has found great confusion amongst engineers and designers with respect to concepts such as a wave with a given recurrence interval and its confidence levels. The risk stated above has nothing to do with the confidence bands that are most often quoted. The confidence bands refer to the accuracy with which the wave with a given return period can be estimated if an infinitely long record is not available. With a wave record of only a few years duration there will be considerable uncertainty about the values of 12,0 m and 12,9 m obtained for H_{100} years and $(H_{mo}^0)^{0.1}$ in the example above. This uncertainty is reflected by the confidence bands.

At this point I would also like to make a plea that the concept of a wave with a given return period be scrapped in all specifications for design. I cannot see any sense in specifying that a structure should be designed for a "100 year wave" if the life of the structure will only be 30 years. Even more ridiculous is the specification that an operation that will last for one month should be designed for a "10 year wave". It makes a lot more sense to specify a wave height with a given risk of being exceeded within the 30 year life of the structure or within the one month of the operation. Let us therefore always specify H_h^r when h is the design life of the structure or the duration of an operation and r is the risk of exceeding H during the period h. In this way the designer and his client will know exactly where they stand and not be lulled into a false sense of security in the case where they have for example designed a structure with a 30 year life for the so-called "100 year wave", without realizing that they face a 26% risk of seeing the design wave within the life of the structure.

Case (ii)

The most commonly quoted confidence bands are those where a model for the long term distribution of wave height is assumed and the accuracy with which the parameters of the distribution can be estimated based on a limited record length, is assessed. The accuracy of the estimate of a wave height with a given probability of exceedance is then mainly a function of the record length. The confidence bands narrow with increasing record length and in the case of an infinitely long record length reduces to zero in which case the problem reduces to Case (i) above.

Confidence bands for a number of the more popular distributions have been established either theoretically or by Monte Carlo simulation. Zucchini and Adamson (1984) have also shown that bootstrap sampling techniques can be successfully employed to estimate confidence bands once an appropriate model for the long term distribution of the appropriate variable (waves in our case) have been selected. Efron (1987) further expanded on this method.

For the purpose of establishing confidence bands it is important to use independent and identically distributed samples. For the data used in this paper such samples could include the maximum H_{m0} recorded per year (8 samples), the maximum H_{m0} recorded in each stormy month (40 samples) or the maximum H_{m0} recorded in each week during the stormy months (149 samples). Assuming that these samples belong to an Extreme I distribution, the confidence with which the most probable value of the 100 year H_{m0} , or $(H_{m0})_{100}^{0.83}$, could be estimated was calculated using the bootstrap technique. The results are summarized in Table 5.

It is interesting to note that if the parent distribution is assumed known, and if maximum use is made of the 8 years of available data, the confidence bands for the most probable value of the 100 year H_{m0} becomes relatively narrow i.e. the value at 95% confidence is only 12% higher than the most probable value.

Cases (iii) and (iv)

In the general case where both the distribution and its parameters must be estimated from a limited data base, strict statistical treatment becomes impossible. The large number of distributions that have been proposed for the long term distribution of wave height and the different goodness of fit criteria that can be used in selecting the best fit model, makes it impossible to assess the certainty whereby a given model can be selected. This has been clearly illustrated earlier. If we add to these the uncertainties pertaining to the

representativeness of the samples, the problem becomes even more complicated. Doubts about the representativeness of the sample stems from such factors as the loss of records during storms, long term variations in wave climate, extreme events occurring that belong to a different parent distribution and did not form part of the sample, etc. Most of these uncertainties can be of the same order of magnitude or larger than those associated with the accuracies with which the parameters of a distribution can be estimated for a few years of data.

TABLE 5: 95% CONFIDENCE BANDS AS FUNCTION OF SAMPLING METHOD

Sampling Method	Number of samples	Probability associated with (H_{mo})	$\frac{(H_{mo})_{100}^{0.63} [95\%]}{(\hat{H}_{mo})_{100}^{0.63}}$
Max per year	8	1 - 1/100 = 0,99	1,35
Max per month in stormy months	40	1 - 1/500 = 0,998	1,20
Max per week in stormy months	149	1 - 1/2166 = 0,9995	1,12

5. Summary and Conclusions

1. There is a tendency for waveriders to malfunction near the peak of severe storms. Care should be taken with every data set to ensure that major storms are not truncated or even totally omitted.
2. The general practice of obtaining design wave heights by fitting distributions to data recorded at 3 hr to 6 hr intervals without regard for the independence of the records still seem to be the best approach to use, especially with short data sets. Correlation between the data will however influence the uncertainty of the estimates as measured by confidence limits or rms errors.
3. The selection of an appropriate model for the long term distribution of wave height still remains the most uncertain part in the process of design wave height determination. Bootstrap techniques can be of some help in this process.

4. It should be remembered that the confidence bands associated with extreme events that can be treated statistically only forms part of the overall uncertainty. In all cases the true confidence bands will be wider.
5. It is recommended that the concept of a wave with a given return period be replaced by a wave with a given risk (r) of being exceeded within the design life (h) of a structure (H_T^r). It should be realized that this wave height is only a most probable value and has an associated confidence interval which can be rather wide and is impossible to accurately assess in typical cases of h and r with the short history of wave recording.

CHAPTER 62

REALIZABLE WAVE PARAMETERS IN A LABORATORY FLUME

E.R. Funke¹, E.P.D. Mansard¹ and G. Dai²

ABSTRACT

In order to establish a sound basis for the methodology deployed for the generation of realistic waves under laboratory conditions, a comparison is presented between numerical and physical realizations derived from the Random Phase and the Random Complex Spectrum method for wave synthesis. The comparisons are made in terms of 12 critical wave parameters, including three wave grouping parameters. The results indicate that, for the physical realizations of the limited conditions tested, the two methods give compatible results which fall within the expected band of variability. All physical waves undergo some evolutionary change during propagation which affects predominantly the spectral characteristics. For physical waves produced by the Random Phase method, this change increases the variability of some wave parameters. A sample analysis of one case, applying second order wave and wave generation theory to a numerical simulation, suggests that certain differences between numerical and physical simulations can be explained by non-linear wave theory.

INTRODUCTION

For the laboratory evaluation of designs for coastal and offshore structures, it is common practice to simulate wave trains which satisfy a given variance spectral density. This simulation can be achieved through a variety of synthesis techniques. Among these are two commonly used Fourier techniques which have been referred to as the Random Phase method (RPH) and the Random Complex Spectrum (RCS) method (Mansard & Funke, 1986). The RPH method is a spectrally deterministic technique whereas the RCS method is spectrally non-deterministic.

¹ Hydraulics Laboratory, National Research Council,
Ottawa, Ont., Canada, K1A 0R6

² Guest Scientist from the Nanjing Hydraulic Research Institute,
Nanjing, China

Both the RPH and the RCS methods are based on the inverse Fourier transform of a given target spectral density. In the case of the RPH method, the square root of the given spectral density (i.e. the amplitude spectrum) is paired with a randomly selected phase spectrum. From this a complex spectrum is produced which is then inverse Fourier transformed to produce a time series of the synthesized wave train. Different random selections of the phase spectrum will produce different time series. If any one of these time series is spectrum analyzed, the spectral density so produced will be smooth and match the target spectrum.

In contrast, the Random Complex Spectrum method creates a situation in which the specified distribution of energy in the frequency domain is preserved only within the bounds of probability. It consists of generating a Gaussian distributed white noise complex spectrum which is then filtered by multiplication with the desired amplitude spectrum. The complex product is then inverse Fourier transformed. Individual time series realizations from this synthesis will produce spectra which are not smooth because of the variability of spectral estimates. Only the average of a large number of sample spectra will match the target spectrum.

Each of the above two methods have their own proponents who justify their use in physical models. However, some controversy has arisen around the question of validity of the RPH method (Tucker et al. 1984, Elgar et al 1985, and Medina & Aguilar, 1985). The essence of the criticism is the claim that the RPH method produces insufficient variability of wave parameters and therefore does not represent nature correctly. One wave parameter of concern is wave grouping.

Perhaps the most important comment which can be made at this point, is that the differences are only noticeable for relatively short wave-record lengths. As the length of a synthesized, non-repetitive time series approaches infinity, the two methods are absolutely identical. Evidently, in practice, one cannot make simulations infinitely long. Any meaningful simulation must be carried out over a finite duration of time and that is where one finds the source of the present problem.

The second point which must enter into the consideration is the question of how well numerical simulations represent the conditions which actually prevail in wave flumes for physical model studies. Although, for modern wave generation systems, the numerical synthesis of a wave record forms the input to the control system of the wave machine, the wave train measured in the flume at different locations, may not carry the same statistical characteristics of its progenitor. Linear wave generation has its own way of affecting a simulation. As long as physical model studies are an essential part of our research and design engineering repertoire, this question is relevant.

Mansard and Funke (1986) carried out a numerical study to evaluate the differences in simulations caused by these two

techniques. By varying the random numbers used in the synthesis, 200 different realizations of a 200 second long time series were simulated numerically from a given target spectrum with a peak frequency of 0.55 Hz. At a scale of 1 in 36, this record length corresponds to a full scale sample duration of 20 minutes, which is a typical record length for full scale wave measurements. The resulting series contained approximately 110 waves and were subjected to several frequency and time domain analyses. Twelve different parameters were computed and then assembled into independent wave parameter lists for subsequent statistical analysis.

The results of the study showed that the differences between the RPH method and the RCS method, in terms of the selected parameters, are small, even for these relatively short wave records. This conclusion was based on a statistical analysis of average, standard deviation as well as maxima and minima of the twelve parameters, computed for 200 realizations of each case.

When waves are produced in a laboratory flume for simulation purposes, it is common practice to adjust the wave generator stroke gain until the waves produced have the specified significant wave height; a condition generally specified by the client. However, waves synthesized by the RCS method must be expected to exhibit variability of variance from record to record, and as a result the significant wave height will also show variability. By adjusting the wave machine stroke gain, one does intervene in the natural process. For the study by Mansard and Funke (1986), each record was rescaled so as to fix the variance of each wave record to that specified in accordance with laboratory practice. On the other hand, in the study presented here, the simulations with the RCS method are performed in two ways, once with rescaling and once without rescaling.

The 1986 study was restricted to only 12 wave parameters which were considered important at that time. This investigation, however, looked at a total of 27 wave parameters, 12 of which are included in this publication. The remainder are to be published in a separate report later. The study presented here complements the 1986 study and, furthermore, adds insight into the question of physical realizability.

EXPERIMENTAL SET-UP

The experimental set-up is shown in Figure 1. Experiments were carried out in a flume of dimensions 1.2 x 1.2 x 67 m. Waves were generated in a depth of 0.7 m and were monitored at a distance of 8.7 m and 25.3 m from the paddle. An effective dissipation of the incident energy was ensured by a mildly sloping permeable gravel beach (1:25 slope) designed to minimize the reflection of long wave components. Previous evaluation of a beach of this type indicated that its average reflection coefficient can be expected to be below 5% for the frequency band from 0.3 Hz to 1.3 Hz.

The wave generator was operated in the piston mode. Much care was used in its calibration to ensure that the wave paddle excursions corresponded to the theoretical values. All wave generation was carried out with the application of linear wave generation theory.

FIGURE 1

SKETCH OF THE EXPERIMENTAL SET-UP

Repeatability tests were carried out on several specimen wave records. The following table gives repeatability values for four different parameters.

TABLE I

Repeatability Results over 22 Tests at $x = 8.7$ m		
	% AVERAGE ABSOLUTE DIFFERENCE	% MAXIMUM DIFFERENCE
H_{m0}	0.64	1.3
$H_{1/3}$	1.00	2.6
H_{max}	1.48	3.1
GF	0.83	3.1

TEST CONDITIONS

The investigation described here was limited to a JONSWAP target spectral density with a peak frequency $f_p = 0.55$ Hz, a peak enhancement factor $\gamma = 3.3$, and a significant wave height $H_{m0} = 0.15$ m.

From the target spectral density, a total of 600 time series were generated using both the RPH and the RCS methods of wave synthesis, i.e.

- 200 time series using the Random Phase method,
- 200 time series using the Random Complex Spectrum method, and
- 200 time series using the Random Complex Spectrum method, with the record variance rescaled to the target value of the variance.

Measurements for physical model tests were initiated after the wave trains had stabilized in the tank. This involved generally a waiting period of 3 minutes after wave generation commenced. Following each test, the tank was allowed to

settle before a new test was started. The measurement duration was fixed to be identical to the recycling period of the synthesized wave trains.

ANALYSIS

The measured water surface elevations for each of the 600 tests were subjected to several conventional and non-conventional analyses. Spectral density analysis was used to demonstrate that the target spectra were achieved with adequate fidelity. Figure 2 gives eight samples of these, two pairs for the RPH and two for the RCS methods. The spectra shown correspond to measurements taken at 8.7 m and 25.3 m.

Twenty-seven different spectral and time domain wave parameters were computed. Of these twelve are presented here. These are:

- f_p the peak frequency as determined from the frequency at which the spectral density is a maximum,
- f_{pD} the peak frequency as determined by the Delft method (IAHR List of Sea State Parameters), :

$$f_{pD} = \frac{\int_{f_1}^{f_2} f \cdot S_{\eta}(f) df}{\int_{f_1}^{f_2} S_{\eta}(f) \cdot df}$$

where f_1 is the first and f_2 is the last crossing of a threshold that is 80% of the spectral peak value.

- $H_{1/3,d}$ the significant wave height by zero down-crossing analysis,

$H_{max}/H_{1/3}$ the ratio of the maximum and the significant wave height as computed from zero down-crossing analysis,

- $\bar{s}_{z,d}$ the average steepness of all waves as computed from zero down-crossing analysis. This is given as:

$$\bar{s}_{z,d} = (1/N) \text{SUM}[H_i/L_i] \text{ for } i=1,N$$

where H_i and L_i are the i th down-crossing wave height and wave period respectively.

- \bar{s}_c' the average crest front steepness as computed from zero down-crossing analysis (Kjeldsen & Myrhaug 1979). This is defined as:

$$\bar{s}_c' = (1/N) \text{SUM}[a_{c,i}/L'_i]$$

where $a_{c,i}$ and L'_i are the i th wave crest and wave crest front length respectively.

- $\bar{\mu}_H$ the average horizontal asymmetry as computed by Kjeldsen & Myrhaug (1979),

$$\bar{\mu}_H = (1/N) \text{SUM}[a_{c,i}/H_i] \text{ for } i=1,N$$

where $a_{c,i}$ and H_i are the i th wave crest and wave height respectively.

- $\bar{\mu}_v$ the average vertical asymmetry. This parameter differs from that given by Kjeldsen & Myrhaug (1979) and is based on a definition suggested by Goda (personal communication), i.e.

$$\bar{\mu}_v = (1/N) \text{SUM}[L_i'/(L_i'+L_i'')] \text{ for } i=1,N$$

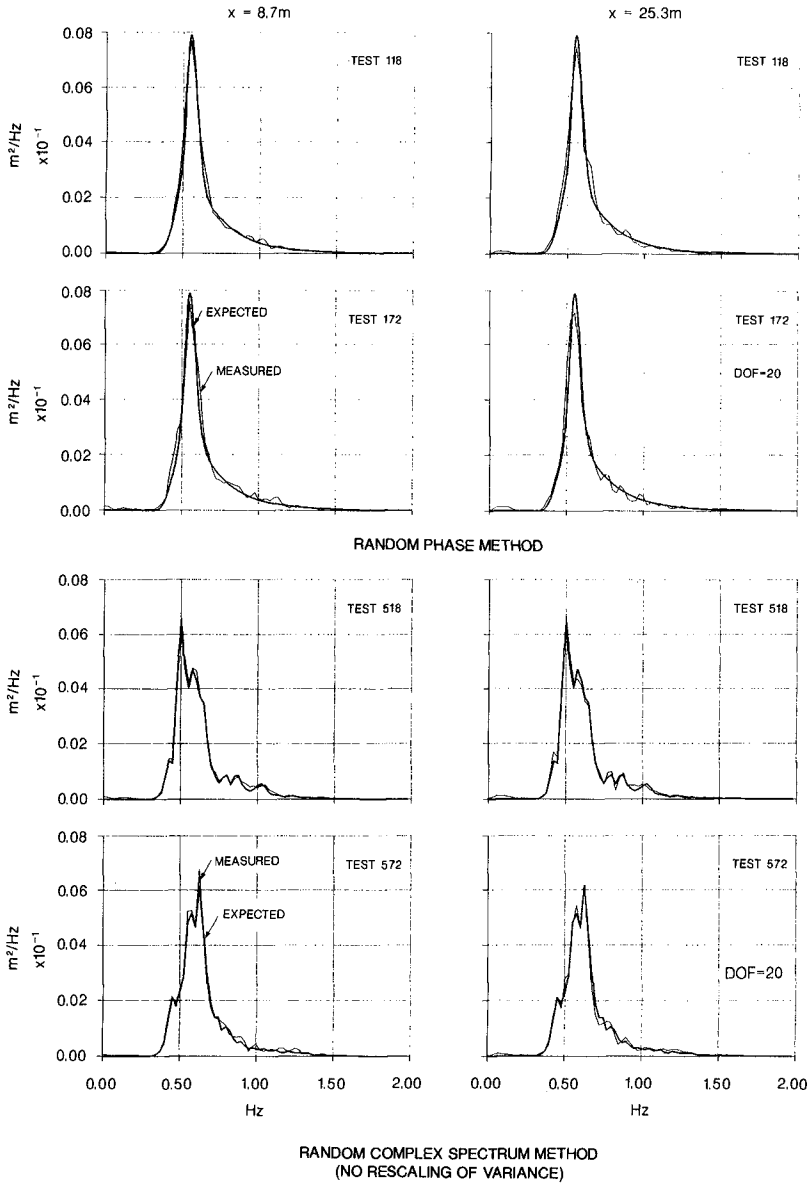

FIGURE 2
REALIZATIONS OF SPECTRAL DENSITIES IN A LABORATORY FLUME
($H_{m0}=0.15\text{m}$ $f_p=0.55\text{Hz}$ $\gamma=3.3$)

FIGURE 3
 STATISTICAL VARIABILITY OF WAVE PARAMETERS

where L_i' and L_i'' are the i th crest front and crest rear wave lengths respectively. However, as Kjeldsen has pointed out (personal communication), this parameter can be expected to assume the value 0.5 under normal laboratory conditions and in the absence of wind and current.

Q_p the Goda peakedness factor (Goda, 1985). This is given as:

$$Q_p = (2/m_0^2) \int_{f_2}^{f_1} f \cdot S_{\eta}^2(f) \cdot df$$

where $f_1 = 0.28$ and $f_2 = 1.38$ Hz.

GF the SIWEH groupiness factor (Funke & Mansard, 1979). This is given as:

$$GF = \sqrt{m_{0,E} / m_0}$$

where $m_{0,E}$ is the zeroth moment of the groupiness spectrum.

$\bar{J}_{1,H}$ the average run length of waves greater than the average wave height \bar{H}_0 , as computed from zero down-crossing analysis (Goda, 1976), and

$\bar{J}_{1,H_{1/3}}$ the average run length of waves greater than the significant wave height $H_{1/3,d}$, as computed from zero down-crossing analysis (Goda, 1976).

The chosen wave parameter values from each wave record were assembled in ordered lists, some of which are illustrated graphically as time series in Figure 3 for the case of a physical realization of a non-rescaled, RCS method synthesized waves as measured 8.7 m from the wave board.

The lists of wave parameters were then subjected to statistical analysis to yield the average, the standard deviation, the maximum and the minimum values.

RESULTS

In order to facilitate comparison, the results of the analysis are presented in graphical form in Figures 4a, 4b and 4c. These are given in terms of the mean, the extrema, as well as the mean + and - one standard deviation. For each parameter the results are placed in three separate groups, i.e.

- results from the RPH method of synthesis,
- results from the RCS method of synthesis but rescaled to force the target variance on each wave record, and
- results from the RCS method of synthesis but without rescaling.

Then, for each group, results are again shown separately for:

- numerical synthesis only,
- a physical realization of the numerical synthesis as measured at 8.7 m from the wave board, and
- a physical realization of the numerical synthesis as measured at 25.3 m from the wave board.

DISCUSSION OF RESULTS

The main conclusions of the study are as follows:

- As could be expected the numerical realizations of the RPH method have no variability for the parameter f_p , and very little variability for f_{pd} and Q_p . In the case of the last two parameters, the small amount of variability must be attributed to computational noise.
- When a wave record synthesized by the RPH method is converted to a physical wave in a wave flume, then the variability of the f_p , f_{pd} and Q_p parameters increases, but will not equal the variability achieved by the RCS method.

FIGURE 4a. STATISTICAL VARIABILITY OF WAVE PARAMETERS

- The mean value and the variability of the parameter $H_{1/3,d}$, as derived by the RPH and the rescaled RCS methods, are almost identical.
- As could be expected, the variability of $H_{1/3,d}$ is significantly larger for the non-scaled RCS than for the rescaled RCS method.
- The following parameters exhibit little differences between the RPH and the RCS method:
 - o $H_{max}/H_{1/3}$ the ratio of the maximum and the significant wave height,
 - o μ_H the average horizontal asymmetry,
 - o μ_V the average vertical asymmetry,
 - o GF the SIWEH groupiness factor,

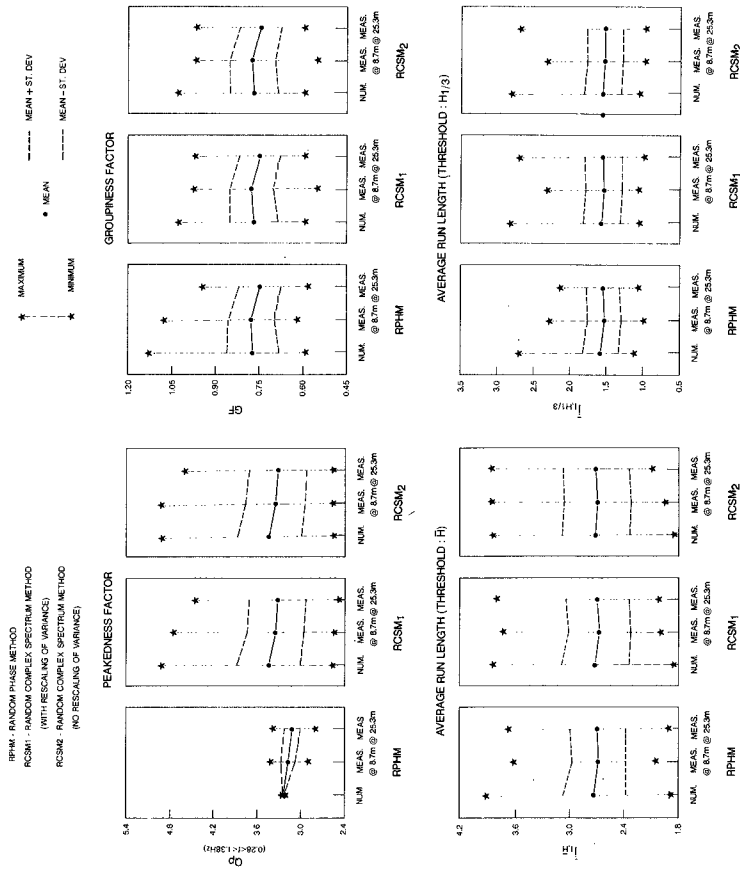

FIGURE 4D. STATISTICAL VARIABILITY OF WAVE PARAMETERS

- $\bar{J}_{1,\bar{H}}$ the run length of waves higher than the average wave height, and
- $\bar{J}_{1,H_{1/3}}$ the run length of waves higher than the significant wave height.

This favourable comparison with regard to wave grouping diminishes one of the concerns expressed by Tucker et al. (1984).

- the conversion of a numerical simulation into a physical realization has a remarkable impact on several parameters whose definition depend on the wave crest. From this it can be concluded that, for the conditions which prevailed for the test under study, the crest

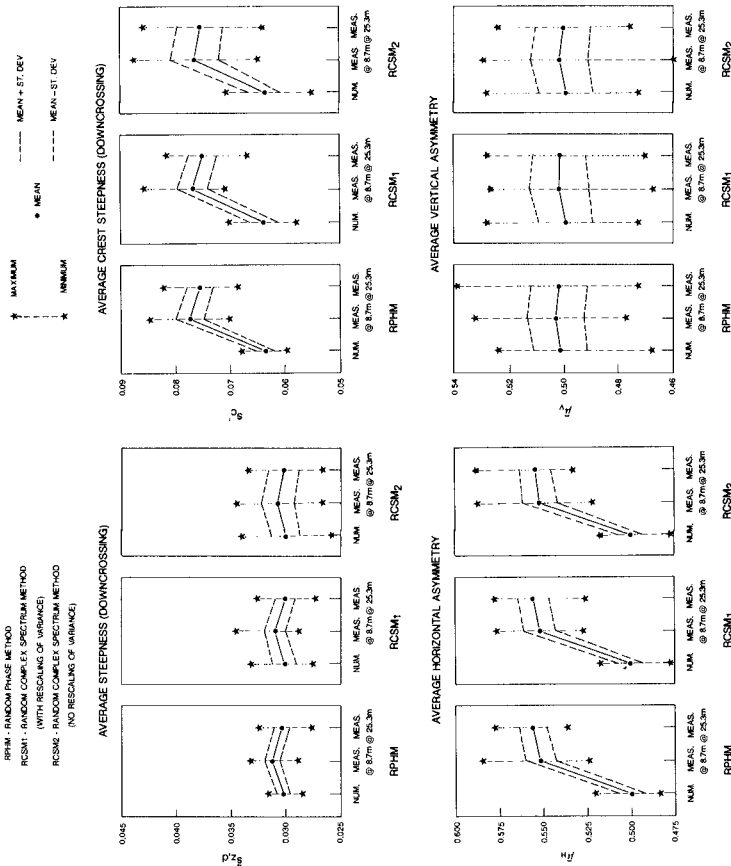

FIGURE 4c. STATISTICAL VARIABILITY OF WAVE PARAMETERS

heights in physical simulations are greater than those obtained by numerical simulations. These parameters are:

- $H_{1/3,d}$ the significant wave height by zero crossing analysis,
 - s'_c the crest front steepness, and
 - $\overline{\mu}_H$ the average horizontal asymmetry.
- There is no significant difference in the average vertical asymmetry $\overline{\mu}_v$ between numerical and physical simulations in the absence of wind and currents. In other words, the physical waves are, on the average, symmetrical.
 - In general, the differences between the RPH and the RCS methods are small for physical simulation. In fact, it can be seen that there is almost as large a difference between two records selected at random from one method than there is between records selected from the two different methods.
 - There is no apparent relationship between the wave run length parameter and the SIWEH groupiness factor. Both evidently measure different aspects of the wave grouping phenomenon. This is apparent from Figure 3.

To further investigate the differences between numerical and physical simulations, an attempt was made to reconstruct one wave train through the application of second order effects. As stated above, the conversion of numerical simulations to physical realizations was undertaken by means of linear wave generation theory. By applying second order wave and wave generation theory to one of the numerical simulations, it was possible to calculate the second order wave components which were naturally locked to the wave and those which were inadvertently produced because of the first order approximation. These were predicted for the one case at the two probe positions (Barthel et al 1983, Sand & Mansard, 1986).

A comparison is made in Figure 5 between this second order reconstruction and the corresponding wave trains measured. From this it is apparent that most of the differences between numerical and physical simulations are predictable. This result also suggests that numerical simulations for wave conditions in the coastal zone should be carried out with the inclusion of second order effects.

CHAPTER 63

Spectral Wave Attenuation by Bottom Friction: Experiments

Ole Secher Madsen¹ and Moises Michel Rosengaus²

ABSTRACT

This paper presents a summary of carefully conducted laboratory experiments on sediment response and resulting wave attenuation for waves, periodic as well as simulating a wave spectrum, propagating over an 18-m-long bottom section covered by a 10-cm-thick layer of 0.2-mm-diameter quartz sand. The results for wave-generated bedform geometry as well as the equivalent Nikuradse roughness are obtained. The results show that the sediment response to the agitation of a wave spectrum may be approximately described by the sediment response to an equivalent periodic wave having the same root-mean-square near-bottom orbital velocity and excursion amplitude as the spectral wave. This equivalent wave, defined by the near-bottom characteristics of the spectral wave, is identical to that derived by Madsen et al. (1988) in the context of dissipation within the wave boundary layer. Although limited by the range of experimental conditions achieved in this study, the results obtained here and in the companion paper suggest a predictive methodology for the evaluation of spectral wave attenuation from knowledge of sediment and wave characteristics.

INTRODUCTION

As waves propagate into waters of finite depth the waves respond to the presence of the bottom, e.g., through shoaling, depth refraction, and energy dissipation, while the bottom, consisting of movable sediment, responds to the presence of waves by exhibiting bedforms. In the present context of wave attenuation, the wave-sediment interaction is of crucial importance since the bottom bedforms and sediment transport caused by the wave motion itself, in turn, determine the bottom roughness and hence the rate of energy dissipation within the bottom boundary layer.

In a companion paper (Madsen et al., 1988) an approximate theory for the turbulent boundary layer flow over a rough bottom and the associated dissipation of energy has been

1 Professor of Civil Engineering, R. M. Parsons Laboratory, MIT, Cambridge, MA 02139, USA

2 Hydraulics Specialist, Instituto Mexicano de Tecnologia del Agua, Jiuetpec, Morelos, Mexico (formerly Graduate student, R. M. Parsons Laboratory)

developed for a wave motion specified by its directional frequency spectrum. While overcoming some of the problems of currently available theories for the evaluation of spectral dissipation by bottom friction, the theory by Madsen et al. (1988) assumes the equivalent Nikuradse roughness of the bottom, k_b , to be known a priori. From the preceding discussion of the response of a movable bed to the agitation by waves it is evident that the equivalent bottom roughness of a movable bed is a function of wave-sediment interaction, i.e., it is a dependent variable.

Based on the limited data of Carstens et al. (1969) and Stefanick's (1979) comprehensive review of experimental data on the geometry of wave-generated bedforms Grant and Madsen (1982) proposed a predictive expression for k_b in terms of sediment and wave characteristics. A major shortcoming of the Grant-Madsen relationship is that it, as others, e.g., Lofquist (1986), Vongvisessomjai (1987) is derived from experimental data obtained exclusively for monochromatic waves. To apply any of the existing relationships for movable bed roughness, in conjunction with a theory for spectral dissipation, to predict spectral wave attenuation by bottom friction therefore requires the determination of the characteristics of a periodic wave which is equivalent to the spectral wave in the context of wave-sediment interaction. To demonstrate that such an equivalent periodic wave does exist and to determine its characteristics are the objectives of the experimental study summarized in this paper.

The philosophy behind the experimental methodology and procedures used in the present study is to measure the attenuation of water waves (periodic as well as simulated spectral waves) propagating over a long section of movable bed and from the measured attenuation of each incident wave component backfigure the appropriate value of the wave friction factor for each incident wave component using the theoretical model for spectral wave attenuation developed by Madsen et al. (1988). From knowledge of the wave friction factor and the incident wave condition, which according to Madsen et al. (1988) is represented by a periodic wave having the same root-mean-square near-bottom orbital velocity and excursion amplitude as the simulated wave spectrum, the Grant and Madsen (1986) relationship between periodic wave characteristics, equivalent bottom roughness, and wave friction factor is used--in reverse--to back out a value of the equivalent bottom roughness, k_b . The geometry of bottom bedforms generated by the waves, whose attenuation was determined, is also determined and related to the wave and sediment characteristics as well as to the measured values of the equivalent bottom roughness, k_b , in order to arrive at a predictive relationship for the equivalent bottom roughness of a movable bed valid for spectral waves.

EXPERIMENTAL SET-UP

Laboratory experiments were performed in a 0.75-m-wide, 0.90-m-deep, 30-m-long wave flume in the R. M. Parsons Laboratory. This wave flume is equipped with a programmable piston-type wave maker and has a 1-on-10 sloping ab-

sorber beach, which in the present experiment was covered by 7.5-cm-thick horsehair mats to further decrease reflections. At the wave maker a trapezoidal wooden ramp provided a smooth transition to a level 10 cm above the flume bottom. The region between the ramp--approximately 3 m from the wave maker--to the start of the absorber beach--approximately 19 m from the wave maker--was covered by a 10-cm-thick layer of very uniform 0.2-mm-diameter Ottawa quartz sand.

The wave maker was programmed to simulate the generation of incident periodic waves, wave groups consisting of two frequency components, and wave spectra. Two different spectral simulation methods were used: one simulating the spectrum as equally spaced frequency components, the other representing the spectrum by different frequency components of equal energy. Although of no fundamental importance to the study it is mentioned for completeness that the spectral shape simulated in our experiments was that of a Neuman spectrum. In the majority of the experiments the water depth above the movable bed test section was 0.60 m.

In order to mobilize the bed material it was necessary to generate waves of large amplitudes and wave lengths. Our standard wave condition corresponded to a 6-cm-amplitude, 2.65-sec-period wave for which $h/L = 0.1$ in the 0.6-m-deep section. Wave group experiments were conducted with frequencies centered around the 2.65-sec-period while this period was taken as the peak period in spectral simulations. Due to limited wave-making capability it was only possible to generate multi-component wave conditions with an energy content equal to half of that of the standard periodic wave. The incident and reflected wave components were determined from surface profile measurements obtained from two three-gauge arrays (Goda and Suzuki, 1976) located 3 m and 18 m from the wave maker.

Bottom bedform geometry was determined photographically by taking pictures of 1-m sections of the bed profile at four stations along the test section. These pictures, including horizontal and vertical scales, were then projected onto a digitizing tablet and analyzed. Using a vertically mounted laser to trace the bottom profile at different distances from the flume sidewalls it was shown that the trace along the sidewalls accurately represented the bedform geometry.

EXPERIMENTAL PROCEDURE

Given the philosophy behind the experiments as outlined in the Introduction the procedure to be followed is in principle quite simple. From the analysis of Madsen et al. (1988) we may write the energy conservation principle for each wave component when only bottom dissipation is considered

$$c_{gn}\rho g a_n \left[\frac{\partial a_n}{\partial x} \right]_{bf} = -E_{d,n} = -\frac{1}{4}\rho f_{wr} u_{br} u_{bn}^2 \quad (1)$$

where, for a finite number of wave frequency components

$$u_{br} = \sqrt{\sum_n u_{bn}^2}$$

$$A_{br} = \sqrt{\sum_n (u_{bn}/\omega_n)^2} = u_{br}/\omega_r \quad (2)$$

defines the representative periodic wave, and

$$u_{bn} = \frac{a_n \omega_n}{\sinh k_n h} \quad (3)$$

Thus, for a single wave component--whether it is alone or one of two or more--we have from Eqs. (1) through (3)

$$\left[\frac{\partial a_n}{\partial x} \right]_{bf} = -f_{wr} \frac{u_{br}}{4g c_{gn}} \left[\frac{\omega_n}{\sinh k_n h} \right]^2 a_n \quad (4)$$

In principle the experimental determination of a_n at two stations, Δx apart, suffices to determine a value of f_{wr} from Eq. (4). In practice, however, life is unfortunately not that simple.

First of all the experimental determination of Δa_n involves the "small" difference between two "large" quantities. As an example we may take the standard periodic wave ($a_n = 6$ cm, $T_n = 2\pi/\omega_n = 2.65$ sec, $h = 0.60$ m) and a friction factor of $f_{wr} = 0.2$ to obtain a change in amplitude of $\Delta a \approx 7$ mm over the 15-m-long test section. While this value of Δa is well above the accuracy with which the individual amplitudes is determined experimentally--estimated to be of the order 0.5 mm--it should be recalled that component amplitudes of the order 1 to 2 cm are used in spectral simulations. Thus, we are in some cases attempting to measure differences of the order a few mm, i.e., approaching the magnitude of uncertainty of each measurement used to determine the difference. For this reason alone it is essential that the experiments be conducted with great thoroughness and repeated several times in order to minimize the effect of experimental errors.

However, other effects in addition to those directly related to measurement accuracy play a role in these experiments. Owing to the requirement of long waves of substantial amplitude--to set the bottom sediment in motion--it can be expected that nonlinear effects come into play. To illustrate this, assume the change of amplitude, Δa_n , to have been determined experimentally over a distance Δx . Formally, we may then write

$$\frac{\partial a_n}{\partial x} \approx \frac{\Delta a_n}{\Delta x} = m = m_{nl} + m_{sw} + \left[\frac{\partial a_n}{\partial x} \right]_{bf} \quad (5)$$

in which m_{nl} denotes amplitude changes associated with nonlinearity, m_{sw} the changes associated with dissipation along the side walls, and $(\partial a_n / \partial x)_{bf}$ is the quantity expressing the contribution of bottom friction, i.e., the quantity we are looking for. A priori we cannot neglect the unwanted contributions, m_{nl} and m_{sw} , in particular when the overall requirement of accuracy is kept in mind.

To evaluate the magnitude of the terms $m_{nl} + m_{sw}$ in Eq. (5) preliminary experiments were conducted for conditions corresponding to a flat bed. The measured amplitude change in these preliminary experiments (denoted by subscript p)

$$\left[\frac{\Delta a_n}{\Delta x} \right]_p = m_p \simeq m_{nl} + m_{sw} + m_{fb} \quad (6)$$

were taken to represent nonlinear and sidewall effects also in the movable bed runs. The bottom friction effect, m_{fb} in Eq. (6), was calculated theoretically using the sediment grain size as the bottom roughness.

For experiments with simple periodic waves the nonlinear effects were eliminated by correcting the wave maker motion as suggested by Madsen (1971). For all other experiments a series of about five preliminary runs were performed to determine the nonlinear and sidewall contributions using Eq. (6). Following the preliminary runs the wave condition was maintained in the flume for sufficiently long time to ensure the bedforms on the bottom to be fully developed (in some cases this took several hours). Several wave measurements were then performed corresponding to fully developed bed conditions with bottom bedform geometry determined between individual wave measurements (to ensure that the bed indeed was fully developed). Combining the preliminary and the fully developed wave measurements, as outlined above, produced experimental results for the isolated effect of wave attenuation caused by bottom friction, which in turn were used in Eq. (5) to obtain friction factors.

SUMMARY OF RESULTS

Since the present results are preliminary in nature due to the limited range of experimental parameters covered, only a summary of the conclusions most significant to application will be presented here. Further details may be obtained from Rosengaus (1987) and in subsequent publications. By comparison of bedform geometry generated by simple periodic and multi-component (spectral) waves it is found that the representative wave defined by Eq. (2) may be used to describe the response of a movable bed to wave agitation.

This conclusion is supported by the results presented in Figure 1a and b which shows measured ripple height, η , normalized by the excursion amplitude of the representative wave, defined by Eq. (2), and ripple steepness (η/λ), respectively, as functions of the sediment mobility parameter ψ'/ψ_c where

$$\psi' = \frac{\tau_b'}{(s-1)\rho g d} \quad (7)$$

is the Shields parameter based on grain size roughness evaluated for the representative wave and ψ_c is the critical value for initiation of sediment motion (see Madsen and Grant, 1976, for details).

For comparison the empirical relationships derived by Stefanick (1979) and used by Grant and Madsen (1982) are

a: Fully developed bedform height for non-monochromatic waves

b: Fully developed bedform steepness for non-monochromatic waves

Figure 1: Comparison of Bedform Geometry.

shown as dashed lines while new relationships derived from this investigation

$$\frac{\eta}{A_{br}} = 0.31 - 0.06(\psi'/\psi_c)$$

$$\frac{\eta}{\lambda} = 0.19 - 0.014(\psi'/\psi_c) \quad (8)$$

are shown as solid lines. As is evident from the results presented in figures 1a and b the agreement between bedform geometry generated by monochromatic and multi-component waves (groups and spectra) is excellent, but tested only within a range of (ψ'/ψ_c) slightly above unity. Use of Eqs. (8) should therefore be limited to values of (ψ'/ψ_c) less than about 3 or, in the terminology of Grant and Madsen (1982), for conditions corresponding to the "equilibrium range." The relatively small difference between the present results for ripple geometry and the predictive relationships by Grant and Madsen (1982) tentatively suggests the use of their relationship for conditions beyond the equilibrium range.

A slightly modified version of the Grant and Madsen (1982) relationship for the equivalent bottom roughness of a movable bed, k_b , as a function of bedform geometry can be used also for multi-component (spectral) waves when these are represented by the periodic wave defined by Eq. (2), i.e.

$$\frac{k_b}{A_{br}} = K \frac{\eta}{A_{br}} \frac{\eta}{\lambda} \quad (9)$$

is found to apply within the equilibrium range with the constant K, originally given as 28 by Grant and Madsen (1982), being replaced by K = 20, when using their empirical relationships for ripple geometry, and by K = 23, when the relationships given by Eq. (8) are used.

Table 1
Spectral Wave Friction Factors

<u>Frequency</u> (rad/sec)	<u>Amplitude</u> (cm)	<u>Near-bottom</u> <u>velocity</u> (cm/sec)	<u>Friction factor</u>
1.634	1.63	6.22	0.199
2.136	1.65	6.04	0.140
2.388	1.49	5.31	0.231
2.702	1.27	4.36	0.142
2.953	1.26	4.18	0.040
3.393	1.30	3.99	0.222
3.958	1.35	3.68	0.267
6.346	1.13	1.19	0.159

In support of this conclusion results from an "equal component amplitude" spectral simulation experiment are presented in Table 1. With a single exception the friction factors obtained for the different frequency components are

remarkably similar (mean value of 0.194 and coefficient of variation 25% when the single exception is excluded). A weighted average of the friction factors listed in Table 1 which preserves total measured energy dissipation (weighting factor u_{br}^2) gives a value of 0.192 (0.176 if the single exception is not excluded). Corresponding to this wave condition the representative wave, defined by Eq. (2), is characterized by

$$u_{br} = 13.06 \text{ cm/s}, \quad a_{br} = 5.86 \text{ cm}, \quad T_r = 2\pi/\omega_r = 2.23 \text{ sec}$$

and use of the Grant and Madsen (1982) empirical relationships for bedform geometry with $K = 20$ in Eq. (9) gives a value of $k_b/A_{br} = 0.68$. Similarly, use of Eq. (8) with $K = 23$ in Eq. (9) results in a value of $k_b/A_{br} = 0.94$. It is important to note here that when the information on relative bottom roughness is used to predict the representative value of the friction factor this must be done using the generalized friction factor relationship given by Grant and Madsen (1982, Figure 3) since this relationship was used (in reverse) when establishing Eq. (9) from experimental values of the friction factor. Thus, with these values of relative roughness use of Figure 3 in Grant and Madsen (1982) yields predicted values of the friction factor of 0.18 and 0.21, respectively, in excellent agreement with the experimentally obtained values. Again, this conclusion is limited by the range of experimental parameters covered, i.e., within the "equilibrium range" of bottom bedforms. Tentatively, however, one may adopt the Grant and Madsen (1982) formulation, with the modification of the form drag term, $K = 20$ in Eq. (9), as indicated by the present results for conditions beyond the equilibrium range.

SUMMARY AND CONCLUSIONS

The results of carefully conducted experiments have been used to show that a representative periodic wave defined by Eq. (2) as the wave having the same root-mean-square near-bottom orbital velocity and excursion amplitude as a wave motion specified by its frequency spectrum may be used in conjunction with empirically derived relationships for movable bed roughness, to predict the equivalent bottom roughness, k_b , from knowledge of wave and sediment characteristics. With knowledge of k_b for a movable bed, the theory developed in the companion paper (Madsen et al., 1988) may be used to predict the spectral wave attenuation due to bottom friction.

It is, however, emphasized that the above conclusion should be regarded as preliminary until further experiments, covering a wider range of experimental parameters, can support its general validity. Thus, the present experiments were limited to one single sand size and the wave conditions were such that only bottom bedforms within the equilibrium range (as defined by Grant and Madsen, 1982) were generated. Presently the experimental investigation is being continued and extended to a finer sand (0.1-mm diameter) with an improved wave generation capability (larger waves). Both of these modifications and extensions

should contribute to the removal of the limitations of the present results.

CHAPTER 64

A Barotropic 3D-Model for the Study of Currents around the Atlantic Coast of the Iberian Peninsula.

I. Rodriguez. Programa de Clima Maritimo. Madrid. Spain
J. Kröhn. GKSS Forschungszentrum Geesthacht, FRG
J.O. Backhaus. Institut für Meereskunde, University of Hamburg, FRG.

Abstract

We intend to present a brief description of the fundamentals of a barotropic version of the 3D numerical model of the Institut für Meereskunde-Hamburg altogether with some results concerning the application of the model to the simulation of tidal currents in the Spanish Atlantic waters.

1 Introduction

In 1984 the Climate Marine Program (PCM) of the Spanish Directorate of Ports and Coasts decided to get involved into the modelling of sea currents induced by tides and winds at the waters surrounding the Iberian Peninsula and the Canary Islands.

The main motivation was the scarcity of data of this kind all along the Spanish coastline, as well as the need for numerical tools as a help in the study of local coastal problems.

We also consider its use as a support for navigation and fishery activities and data banking assimilation. P.C.M. established this year an agreement of technical assistance with two German institutions: the G.K.S.S.-Forschungszentrum at Geesthacht and the Institut für Meereskunde in Hamburg (IFM).

The purpose of this agreement was the implementation of a barotropic version of the 3D model developed by the IFM in the area of interest for PCM.

The strategy contemplated two stages.

The first one accomplished the implementation of a large scale barotropic model for tidal and wind induced dynamics.

A winter episode has been simulated. And charts of tidal and wind induced currents have been produced. This model will also provide consistent boundary conditions for smaller scale regional models.

PCM in a second stage will apply the model to smaller scale areas incorporating new features of the original version such as the baroclinic pressure gradient.

2 Model Description

The barotropic three dimensional numerical model is

based on a two-time level semi-implicit scheme.

Momentum equations in S-E and W-E directions as well as the continuity equation have been vertically integrated for each of the horizontal layers in which the water column is divided.

For the layer of thickness "h" the equations are:

- Momentum balance

$$\frac{\partial U}{\partial t} - fV + gh \frac{\partial \tau}{\partial x} = X + \Delta \left[A_v \frac{\partial}{\partial z} \left(\frac{U}{h} \right) \right]$$

$$\frac{\partial V}{\partial t} + fU + gh \frac{\partial \tau}{\partial y} = Y + \Delta \left[A_v \frac{\partial}{\partial z} \left(\frac{V}{h} \right) \right]$$

- Mass balance

$$0 = \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \Delta W \Leftrightarrow \frac{\partial \tau}{\partial t} = - \left(\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} \right)$$

U, V - Horizontal components of transport for the layer

\bar{U}, \bar{V} - Horizontal components of transport for the whole water column. (Vertically Integrated)

ΔW - Vertical velocity difference between top and bottom of the layer

τ - Free surface elevation.

f - Coriolis parameter.

g - Acceleration of gravity

A_v - Vertical eddy viscosity coefficient.

The most important terms involved in the equations have been explicitly pointed out:

- Local Inertia terms
- Coriolis force
- External horizontal pressure gradient
- Vertical diffusion terms expressed through the eddy viscosity analogy.

Additional terms like those of horizontal diffusion and advection are indicated by the letters X, Y.

The main features of the numerics can be summarized as follows (Backhaus 1983, 1985):

a) In order to avoid instabilities arising from a forward-in-time approximation of the Coriolis terms a second order approximation has been used for those terms. This introduces a coupling of spatial derivatives of the free surface elevation in both momentum equations through a rotation operator.

By doing this additional boundary conditions need to be defined when computing cross derivatives of the free surface elevation in the vicinity of solid boundaries.

b) Advective and horizontal diffusion terms are solved explicitly. Advective terms are updated in a Lagrangian way by means of a vector - upstream scheme.

c) A semiimplicit treatment of the free surface elevation has been used in all terms involving this variable.

This allows the scheme to get free of the stringent limitation for the time-step given by the Courant-Friedrichs-Lewy stability criterion, as would be the case if the external gravity waves were approximated in an explicit way ($\Delta t < \Delta L / \sqrt{2gh}$).

d) The model considers the horizontal eddy viscosity coefficient as time and space dependent.

An implicit additional system has been introduced for the vertical diffusion terms.

This has been done because once that grid size and layer thickness have been fixed, the stability criterion for an explicit approximation of those terms would represent an artificial upper limit for the vertical eddy viscosity coefficient ($A_v < \Delta z^2 / (2\Delta t)$).

As a consequence, unrealistic description of the flux could take place when a high rate of vertical momentum transfer is required, as would be the case when severe wind forcing is being simulated.

e) A semi-implicit formulation for the quadratic bottom stress is introduced for the sake of numerical stability.

f) Spatial derivatives are centered in time (Crank-Nicholson approach) which leads to a scheme essentially neutral with regard to damping of amplitudes.

The sequence of advancing one time-step proceeds in this way:

First, the horizontal elliptic system for the free surface is obtained by replacing the momentum divergence terms in the vertically integrated equation of continuity (vertical diffusion terms cancel out).

The system is solved by means of an iterative procedure (successive over-relaxation algorithm).

Once that the free surface elevation at the new time level is known, an interim solution for transports can be computed from the pressure gradient terms and all other terms explicitly treated.

Finally, the vertical implicit system involving layer

transport for each water column is established. The equation system is solved by means of a gaussian algorithm.

Boundary conditions are introduced into the model via the coefficients of the free surface elevation system.

Open boundary tidal constants for several harmonics are obtained from the global oceanic model of Schwiderski (1° size).

3 Details of the Model

The horizontal grid used for the model is of the type Arakawa-C. It has the pressure points and transport points half a grid size apart. (Fig. 1)

The horizontal grid size is 12' in latitude and 20' in longitude which means an approximate medium length for the area of about 25 Km.

The real topography for the area has been considered, after an smoothing process up to a depth of 5 Km. (Fig. 2)

The water column has been divided into six vertical layers.

The layer boundaries are: 30, 100, 200, 600, 1500, 5000 meters. The bottom layer thickness accommodates to the sea bottom.

The time step is 20 minutes which gives a CFL factor of about 13.

The performance of the model on an IBM 3090-150 computer is 1 day simulation equivalent to 3.5 CPU minutes.

4 Results

Verifications runs have been carried out with single tidal harmonic components: M2 and S2.

After obtaining stationarity the results of amplitude and phase were compared with the observed ones for points placed along the coast and in the deep sea zone (tidal gauges).

The model behaves very well, producing results very close to the observed ones as it is shown in the graphics included. (Fig. 3)

In order to attain the stationarity of the fortnight spring-neap cycle the model was run for several months with those two tidal harmonics.

A medium factor of about two has been obtained when comparing the tidal ranges of spring to neap tides. (Fig. 4)

At first glance, from the huge ranges obtained high velocities could be expected in the area. This is only true in

the near shore of Bay of Biscay, for as the main part of the domain is deep sea the velocities in the surface layer for the spring hypothesis are less than 0.2 Knots. (Fig. 5)

The graphic output for this spring-neap tidal analysis has been made by drawing the tidal ellipses for several points in the area. (Fig. 3)

The tidal ellipses represent the curve described by the extremity of the velocity vector of each point along a tidal cycle referred to an arbitrary zero time (Highwater at Cadiz)

As, in the Bay of Biscay the velocities are much greater than in the rest of the domain the tidal ellipses in this zone have been removed for the sake of clarity. (Fig. 7, 8)

An interesting feature of the tidal ellipses pattern is the change of sense of rotation from clockwise in the shelf of the Bay of Biscay to anticlockwise in the rest of the area. (Fig. 6)

Other intering points to be mentioned are the two distorted north-south oriented tidal ellipses along the iberian coastline which coincide with two topographic bumps in this zone; and the distorted shapes of tidal ellipses polarized in N-E direction in the area of Madeira and Canary Islands.

This last point requires further explanation, but it seems coincident with the observed pattern in the Canary Islands. (Fig. 6)

There is no observed change of sense of rotation for the ellipses along the water column. The huge thickness (3.5Km) of the bottom layer can overshadow this feature. The most noticeable effect of friction is on the Bay of Biscay shelf where it causes the transition to more open ellipses. (Fig. 6, 7, 8)

5 Conclusions

- . Fine scale barotropic 3-dim. model set up and verified
- . Sea - level variation within 5 - 10% of observed values.
- . Not expected large variation of tidal ellipses (shape sense of rotation and alignment with topography)
 - Madeira/Canary Is.: currents almost linearly polarized.
 - Bay of Biscay: change from anti-clockwise to clockwise rotation
 - Off Iberian peninsula: topographic bumps induced rectilinear distortion of ellipses
 - Bay of Biscay shelf: friction caused transition to more open ellipses
- . Model output:

- Simulation of a winter episode involving the five most significant partial tides (M2, S2, N2, O1, K1) and actual wind stress. The latter obtained from six-hourly surface pressure field from the ECMWF.
 - Production of Tidal Atlas for water levels and currents
 - Boundary values for finer scale regional models (e.g. fisheries, pollution, ...)
- . Develop regional barotropic models
 - . Develop large scale/regional baroclinic models

Kinematics of Breaking Waves in Coastal Regions

William J. Easson¹, Matthew W.P. Griffiths² and Clive A. Greated³

Waves breaking on various slopes in a wave flume are examined. Plunging and spilling breakers are considered. The parametric results show the consistency of the measurement and the independence of scale. A method is given for predicting the maximum breaking height for a wave of known period in a known depth. The velocity is measured to the crest of the wave and comparisons with numerical and analytical solutions demonstrate the shortcomings of many of the established methods of predicting wave kinematics.

Introduction

Breaking waves are of significant importance in the design and understanding of many aspects of Coastal Engineering such as breakwaters, bed movement and inshore construction. Yet the kinematics of these waves are not fully understood despite considerable advanced theoretical and numerical work (e.g. New et. al., 1985). Mathematical models are limited in several ways at present. For example, although deep and shallow waves may be modelled it has not been possible to include changes in bed topography such as linear slopes. Also, the flow field becomes complex when the plunging jet of a breaker hits the forward face making the spilling or surging breakers difficult to model.

Experimentally, the measurement of kinematics is complicated by the two-phase situation which exists above the still water level precluding the use of many standard velocity probes. For this reason mathematical models have usually been inadequately compared with surface profiles.

Due to the difficulty of obtaining breaking wave kinematics, designers have tended to rely on the tried and tested industry standards such as Stokes and Cnoidal theory or Dean's stream function. Recently, higher-order versions of Dean have been available, applicable to larger waves (Chaplin, 1980). All of these assume two dimensional, regular non-breaking waves and necessarily provide limited

descriptions.

Furthermore none of the above methods can give a reliable limiting wave height and the question of whether the 'design wave' might be breaking is dependent on data gathered from elsewhere on height over depth ratios (Griffiths et al, 1987). For this reason several companies have commissioned site-specific studies at the Edinburgh

Fluid Dynamics Unit to discover if the design wave was a breaker and if so what its kinematics were (Birkinshaw et. al., 1988).

This paper will look at spilling and plunging breakers on beds of various slopes in terms of their parameterisation and internal kinematics. A method of using these results will then be proposed.

Experimental method

Regular waves are generated in a narrow tank by a computer-controlled absorbing wavemaker. The wavemaker is in 'deep' water (0.9 m) and the waves are run up a slope of variable degree. For gentle slopes and flat beds an initial steep slope is used (fig. 1).

The velocity measuring technique is Laser Doppler Anemometry. The non-intrusive system records the frequency of variation of light scattering intensity as minute seeding particles pass through the crossing volume of two laser beams. The application of this technique to breakers may be found in Easson & Greated (1984). The method of signal analysis allows measurements up to the crest of the breaking wave which is not common in most systems but will be shown to be of great importance.

Wavelength, height, and velocity were measured using still photography and a video-camera. (figs. 2, 3).

Results

(a) Parametric

The wave parameters measured were deep water height (H_0), breaking height (H_b), breaking depth (d_b), maximum crest elevation (H_{1b}) and trough depression (H_{2b}) wavelength at breaking (L_b) and velocity at breaking (C_b) (see fig. 4). The breaking point is when the crest first becomes vertical. For ease of presentation and application of the results the deep water steepness ($S_0 = H_0/l_0$) has been used as the reference axis. This has been shown to be useful and valid over the range $0.015 < S_0 < 0.115$ in a previous publication (Griffiths et al, 1987), as would be expected since Froude scaling applies here. Furthermore no correction factors are required in applying these results to full scale waves.

The range of slopes considered is 1:15, 1:30, 1:50 and flat bed. Most of the waves produced spilling breakers but the longest waves on the 1:30 slope (small S_0) and most of the waves on the 1:15 slope became plunging breakers.

The first plot (fig. 5) shows the depth at which the waves broke. All length scales have been non-dimensionalised by the deep water wavelength so $d_b' = d_b/gT^2$. This shows that the depth of breaking is independent of slope or period and is purely a function of deep water steepness.

The limits are as expected with the graph passing through zero (no height, no breaking) and tending towards the deep water breaking limit ($S_0 \approx 0.14$) as the breaking depth increases. Figure 6 shows the breaking wave height which is also independent of slope or period and tend towards a deepwater limit of 0.022 at $S_0 = 0.142$. This has been compared with the regular criteria of $H_b' = 0.027$ and the irregular limit of $H_0' = 0.020$. (Ochi and Tsai, 1983).

It is possible, using figs 5 and 6, to read off the breaking wave height given the design parameters of depth and period. For example, a 12.5s wave in a depth of 25 m (typical North Sea) gives $d' = d/gT^2 = 0.016$. From fig. 5, $S_0 = 6.0$ which from fig. 6 gives $H' = 0.011$. Therefore the breaking wave limit height is $H_b = gT^2 \times H' = 16.8$ m. If hindcasting has predicted a height greater than this then the wave will be breaking.

Designers have often used the criterion $H_b/d_b > 0.78$ to determine whether a wave is breaking. This is derived from shallow water solitary wave theory (Munk, 1949) and should not be used for intermediate depths. Figure 7 shows H_b/d_b against S_0 for our results. Previously (Griffiths et al, 1987) the 1:30 results were shown to match the results of other investigators on this slope; they also extended the range to deeper water. Weggel (1982) proposed an empirical upper limit based on the 1:30 slope results. Several significant points may be drawn from this figure. Firstly, the flat bed results tend to the solitary wave limit at small S_0 and the Weggel line is overly conservative. Secondly, the H/d ratio is slope dependent - a fact which is not apparent from figures 5 and 6. Finally, the Weggel line cannot be applied to slopes greater than 1:30 as the plunging breakers here exceed the H_b/d_b ratio predicted.

Svendsen and Buhr Hansen (1976) plot wavelength over depth at breaking as a function of deep water steepness. The results here (fig. 8) confirm the slope of Svendsen's empirical mean value line and extend the range of results towards the deep water limit.

(b) Kinematic results

Velocities were measured under the crest of the wave at a range of elevations from the bed to the crest peak at the instant of breaking. Figure 9 shows the velocity variation from bed to crest of five wave frequencies breaking at a particular depth (185 mm) on a 1:50 slope. The most important general characteristic is the large increase in velocity in the crest where the graph steepens considerably. Thus although the near bed velocities are as expected the crest velocities differ considerably from non-breaking waves. The curvature of the graph is greatest for the short waves which have lower velocities below SWL. The group of points to the right of the graph are the five celerities associated with the frequencies studied, plotted at the maximum elevation of the crest. In each case the velocity curve tends towards the celerity at crest indicating that this is the maximum velocity (although it may only pertain to a very small fraction of the crest volume) and that the condition $v = c$ does indeed represent a useful criterion for wave breaking.

Figure 10 shows the velocity under the crest of a 1 Hz wave breaking at 185 mm depth for different slopes. There is no significant difference between the 1:50 and 1:30 results but higher velocities were measurable for the 1:15 slope due to the larger volume of water

travelling at velocities around c in the plunging jet. (c.f. figures 2 & 3). The plunging breaker was also slightly higher than the others.

Finally, the quality of these results has enabled a direct comparison with some of the established theories. This is only possible when crest values can be obtained. The lack of crest values invalidates the comparisons made by previous investigators as this is where the major differences between breakers and non-breakers arise. Figure 11 shows the velocity variation with elevation for one particular wave but the trends are typical over the full range of conditions investigated. The comparisons are with Linear, Stokes V and Deans V and IX. (We are grateful to Professor J. Chaplin for the comparison with Deans IX (Chaplin, 1980)). The measured velocities tend towards the indicated celerity/height point and the best fit curve has been drawn. The Stokes V has also been indicated by a full curve. Interestingly, the linear theory gives a better fit than Stokes in the crest. The two Deans solutions are better approximations with the ninth giving a significant improvement in the crest. However, even this falls 20% short of the maximum expected velocity. Note that all the theories tend to over-predict the velocity below SWL.

Conclusions

By testing a range of frequencies, Froude scaling has been shown to apply to breaking waves. The parametric results have shown good agreement with those of other experimenters and have usefully extended the range of measurements. A method has been presented for the evaluation of limiting wave heights in the design of offshore structures using graphical procedures. The H/d ratio for breaking is slope dependent but is only significantly so for shallow/plunging breakers. Throughout the range measured the velocity in the crest tends to a maximum equal to the celerity at the highest point of the wave. The established theories tend to underestimate the crest velocity and overestimate the velocities below SWL.

It is important to remember, in the application of these results, that the two-dimensional, regular wave assumption has been made, as is the present industry practice. A project is currently under way, at Edinburgh University, using the instantaneous full-field anemometry technique known as Particle Image Velocimetry (PIV) (Gray & Greated, 1988) to measure the velocities under irregular breaking waves.

Acknowledgements

Mr. Griffiths is a postgraduate student in receipt of a CASE studentship with B.P International. The authors would particularly like to acknowledge the help and access to industrial procedures afforded by B.P. This project is part of the managed Fluid Loading Programme of MTD Ltd. We are also grateful for the encouragement and interest shown by various members of that organisation.

CHAPTER 66

WAVE GROUP ANALYSIS BY THE HILBERT TRANSFORM

Robert T. Hudspeth, M.ASCE*
Josep R. Medina, M.ASCE**

ABSTRACT

A methodology based on linear theory is presented for analyzing wave groups from a random sea representation in the complex plane. A wave height function $[H(t)]$, a local frequency function, $[\Omega(t)]$, and an orbital velocity function $[V(t)]$ are defined from the Hilbert transform of the sea surface elevation. Envelopes computed by the Hilbert transform are compared with the SIWEH. A three axes representation of the mean lengths of runs of waves is employed to compare the lengths of runs computed by the discrete wave method with runs computed by the Hilbert transform method.

INTRODUCTION

The presence of groups of waves in random seas and the corresponding variability of setback along the coast can produce low frequency resonances in the coastal zone (see Battjes (1988) and Bowers (1988)). Tucker (1950) noted that long waves nearshore were caused by wave groups. Since Goda (1970) demonstrated that random ocean waves have a natural tendency to form groups of waves that are larger for more peaked spectra, a variety of observations and theories of wave groups for engineering applications have been developed.

Engineering Interest

Hsu and Blenkarn (1970) pointed out that slow drift oscillation of vessels and mooring forces are related to the sequence of waves in random seas. Ewing (1973) noted that ships can capsize or be damaged by severe motions caused by high wave groups. Johnson et al. (1978) and Bruun (1985) described how wave groups can have a significant affect on the stability and behavior of rubble mound structures.

Barthel et al. (1983) observed that wave groups generate second order long waves in wave flumes when random wave generators are used. Medina and Hudspeth (1987) showed that wave grouping characteristics are strongly related to the statistical variability of the sea state parameters and,

therefore, the uncertainty of wave climates estimated from records can be influenced by wave groupiness. Burchart (1979) and Longuet-Higgins (1984) introduced the concept that wave grouping characteristics in random seas is a significant design element that should be taken into consideration in the design of coastal and ocean structures.

Theories

Although Rice (1954) provided a compact theory for an analysis of the envelopes in random signals and Tucker (1950) demonstrated the importance of the groups of high waves in the generation of coastal long waves and harbor resonance, Goda (1970) was the first to give a simple methodology for analyzing the presence of wave groups in random seas. Goda (1970) introduced the length of runs of waves to measure wave groups and defined a spectral peakedness parameter, Q_p , which indicated that larger wave groups are associated with higher values of Q_p . The basic Goda methodology has been the most widely used to analyze wave groups from real ocean records.

Nolte and Hsu (1972) and Ewing (1973) proposed to analyze wave groups by an envelope function. Funke and Mansard (1979) introduced the Smoothed Instantaneous Wave Energy History (SIWEH) method and an associated Groupiness Factor, GF, to characterize wave groups. Kimura (1980) proposed a Markov chain model to predict the probability density function (pdf) of the length of runs. Goda (1983) found that observations of long-travelled swell waves in the Pacific Ocean agreed quite well with the Kimura theory. Battjes and Vledder (1984) also observed that wave groups in the North Sea were in agreement with the Kimura predictions.

Longuet-Higgins (1984) employed the envelope theory of Rice to demonstrate the similarities between the formulas given by Kimura (1980) for discrete waves and those given by Rice (1954) for envelopes. Medina and Hudspeth (1987) demonstrated the similarity between the SIWEH method and the square of the envelope. They also found that the Goda peakedness parameter, Q_p , and a new parameter, Q_e , provided a relationship between the variability in the variance of the time series and the spectrum of the envelope.

Linear Assumption

Rye (1982) provided a lengthy review of the methodologies and observation of wave groups in random seas and concluded that all of the significant characteristics of wave groups in records of sea surface elevation could be obtained from the variance spectrum. The linear hypothesis of wave groups was also supported by the results of Elgar et al. (1984, 1985) for water depths greater than 10 meters. These observations and those provided by Battjes and Vledder (1984) justify the assumption that the linear hypothesis can correctly analyze wave groups from one-dimensional records in deep water.

If we assume that wave groups in random seas may be analyzed by an ergodic Gaussian stochastic model, then the corresponding variance spectrum contains all of the information required. Medina and Hudspeth (1987) proposed to analyze random waves in the complex plane by using the Hilbert transform to describe the orbital movement of points in the sea surface. They introduced a wave height function, $H(t)$, a local frequency function, $\Omega(t)$, an orbital velocity function, $V(t)$, and other functions to describe random waves in the complex plane. Here we examine the stochastic proper-

ties of some of these functions and introduce some new techniques to characterize wave groups from real ocean records.

WAVE ENVELOPE ANALYSES

Assuming that the vertical displacement of a point in the sea surface, $\eta(t)$, is a realization of an ergodic Gaussian process defined by its one-sided variance spectrum, $S_\eta(f)$, it may be approximated by

$$\eta(t) = \sum_{m=1}^M R_m \cos(2\pi f_m t + \theta_m) \quad (1)$$

where M = the total number of discrete Fourier components; R_m and f_m = the amplitude and frequency of the "mth" wave component, respectively; and θ_m = a random phase angle uniformly distributed in the interval $U[0, 2\pi]$. Tuah and Hudspeth (1982) and Medina et al. (1985) used the following relationship between the amplitude and the variance spectrum:

$$R_m^2 = C_m S_\eta(f_m) \Delta f_m = -2 \ln(U_m) S_\eta(f_m) \Delta f_m; \quad m = 1, 2, \dots, M \quad (2)$$

where U_m = a random variable uniformly distributed in the interval $U[0, 1]$; C_m = a chi-squared random variable with two degrees of freedom; and Δf_m = a discrete frequency interval in the variance spectrum.

Bendat and Piersol (1986) define the Hilbert transform of $\eta(t)$ as

$$\hat{\eta}(t) = \sum_{m=1}^M R_m \sin(2\pi f_m t + \theta_m) = \sum_{m=1}^M R_m \cos\left(2\pi f_m t + \theta_m - \frac{\pi}{2}\right) \quad (3)$$

and an analytic signal or complex-valued function as

$$AF(t) = \eta(t) + j\hat{\eta}(t) = A(t) \exp[j(\theta(t) + \phi)] \quad (4)$$

where $j = \sqrt{-1}$; $\eta(t)$ = a real signal; $\hat{\eta}(t)$ = its Hilbert transform; $A(t)$ = the amplitude of the envelope; and $[\theta(t) + \phi]$ = a phase angle. The Hilbert transform may be implemented exactly in the frequency domain when $\eta(t)$ is periodic (FFT simulations) and may be implemented approximately in the time domain using the optimum Hilbert filters given by McClellan et al. (1979).

A schematic representation of a wave record in the complex plane is illustrated in Fig. 1 where $\eta(t)$ and $\hat{\eta}(t)$ are the vertical and horizontal displacements, respectively, of a point in the sea surface. A wave analysis in the complex plane provides definitions of instantaneous functions of variables which control the process and which have physical interpretations. The instantaneous functions of wave height [$H(t)$], frequency [$\Omega(t)$], and orbital velocity [$V(t)$], may be defined as follows:

$$H(t) = 2A(t) = 2[\eta^2(t) + \hat{\eta}^2(t)]^{1/2} \quad (5)$$

$$\Omega(t) = \frac{1}{2\pi} \frac{d}{dt} \{\text{ARCTAN} [\hat{\eta}(t)/\eta(t)]\} \quad (6)$$

$$V(t) = 2\pi A(t) \Omega(t) = \pi H(t) \Omega(t) \quad (7)$$

Note that these functions are constant values for regular waves.

Fig. 1. Representation of the Orbital Movement of a Point in the Sea Surface.

WAVE HEIGHT FUNCTION

It is of interest to compare the envelopes computed by the Hilbert transform method with the SIWEH method.

Funke and Mansard (1979) introduced the Smoothed Instantaneous Wave Energy History (SIWEH) method to estimate the low frequency component of $\eta^2(t)$ in their analyses of the slow oscillations of floating structures. The objective of the SIWEH filters was to isolate the low frequency components of $\eta^2(t)$. Medina and Hudspeth (1987) demonstrated that the squared-wave height function, $H^2(t) = 4A^2(t)$, is the target function which exactly isolates the low frequency components of $\eta^2(t)$ and can be interpreted as eight times the instantaneous variance function.

For linear random waves, $\eta(t)$ and $\hat{\eta}(t)$ are independent (see Pinkster, 1984); $A^2(t)$ and $H^2(t)$ are chi-squared distributed with two degrees of freedom; and, therefore, $A(t)$ and $H(t)$ are Rayleigh distributed with the following properties:

$$\sigma[H^2(t)] = E[H^2(t)] = 8 m_0 \tag{8}$$

$$E[H(t)] = \sqrt{2\pi m_0} \tag{9}$$

$$\sigma[H(t)] = \sqrt{(8 - 2\pi) m_0} \tag{10}$$

where $\sigma(\cdot)$ = variance; $E(\cdot)$ = expectation operator; and

$$m_0 = \int_0^\infty S_\eta(f) df = \sigma^2[\eta(t)] \tag{11}$$

From Rice (1954), Nolte and Hsu (1972), Bendat and Piersol (1986), and Medina and Gudspeth (1987), the spectra of $H(t)$ and $H^2(t)$ are approximately given by

$$S_H(f) \doteq (8 - 2\pi) m_0 \Gamma_\eta(f) ; S_{H^2}(f) \doteq (64 m_0^2) \Gamma_\eta(f) \quad (12a,b)$$

$$\Gamma_\eta(f) = \frac{2}{m_0} \int_0^\infty S_\eta(f+x) S_\eta(x) dx \quad (13)$$

where S_H = the variance spectrum of $H(t)$; and $S_{H^2}(f)$ = the variance spectrum of $H^2(t)$; and $\Gamma_\eta(f)$ = the spectral density function (unit variance).

An exact instantaneous variance function, $H^2(t)/8$, can be determined for long periodic random realizations by implementing the Hilbert transform in the frequency domain. In the time domain, an approximate temporal Hilbert filter given by McClellan et al. (1979) with 95 points (Pierce, 1985) can be used. The output, using this approximate temporal filter, will be noted by $H_p^2(t)/8$.

The Hilbert filter method is an alternative to the SIWEH method introduced by Funke and Mansard (1979) and also to the LVTS method proposed by Thompson and Seelig (1984). Figures 2 and 3 compare these methods for relatively broad and narrow spectra, respectively. Figure 2 compares the exact FFT [$H^2(t)/8$] and the approximate temporal [$H_p^2(t)/8$] with the SIWEH(t) for an NSA-FFT simulation of a relatively broad-banded JONSWAP spectrum ($\gamma = 1$, $f_p = 0.1$ Hz). Figure 3 compares the same functions for a relatively narrow-banded JONSWAP spectrum ($\gamma = 10.0$ and $f_p = 0.1$ Hz).

Fig. 2. Comparison between the SIWEH, the Exact FFT Hilbert Transform [$H^2(t)/8$], the Approximate Temporal Filter [$H_p^2(t)/8$], and $\eta^2(t)$ for JONSWAP ($\gamma = 1.0$, $f_p = 0.1$ Hz).

Fig. 3. Comparison between the SIWEH, the Exact FFT Hilbert Transform $[H^2(t)/8]$, the Approximate Temporal Filter $[H_p^2(t)/8]$, and $\eta^2(t)$ for JONSWAP ($\gamma = 10$, $f_p = 0.1$ Hz).

Figure 2 demonstrates that $H_p^2(t)/8$ is an excellent approximation to $H^2(t)/8$ while SIWEH(t) is a relatively poor estimator of $H^2(t)/8$. However, real records are not free of noise and it is necessary to examine the sensitivity of these methods to external noise. If we define an error function $\epsilon(t)$ as

$$\epsilon(t) = \left[\left\{ \begin{matrix} H_p^2(t)/8 \\ SIWEH(t) \end{matrix} \right\} - H^2(t)/8 \right] / m_0 \quad (14)$$

then the magnitude measured by the standard deviation $[\sigma(\epsilon)]$ and the correlation coefficient $[r_{\epsilon H}]$ between $\epsilon(t)$ and $H^2(t)/8$ can be used as parameters to indicate the goodness-of-fit of each method.

Figure 4 compares the mean values of $\sigma(\epsilon)$ and $r_{\epsilon H}$ from 40 realizations using NSA simulations and the JONSWAP spectra with 10% (variance) of white noise. The average standard deviation $[\bar{\sigma}(\epsilon)]$ is less than 2% for the temporal Hilbert filter $H_p^2(t)/8$ with no noise, but rises to 45% when 10% of spectral variance is noise. The SIWEH(t) method using a Bartlett window smoothes the envelope giving larger negative average correlation coefficients $r_{\epsilon H}$ for lower values of the peak enhancement factor γ (i.e., wider spectra).

Fig. 4. Comparison between Temporal Hilbert Filter and SIWEH for 40 NSA Simulations of JONSWAP Spectra with Noise (10% Variance).

Figure 5 compares the mean and standard deviations of the SIWEH Groupiness Factor, GF, with the peakedness parameter, Q_e , for 40 NSA realizations without noise and with 10% noise. The Groupiness Factor, GF, is defined as the relative standard deviation of the estimated variance function to the variance of the process. The theoretical lines denoted by $GF_0 \pm \sigma$ correspond to sample spectra of $H^2(t)$ that are, approximately, chi-squared distributed with two degrees of freedom. For NSA simulations, this theoretical approximation tends to underestimate the coefficient of variation of GF_0 . The Groupiness Factor, GF, increases with Q_e indicating that there is less smoothing of $H^2(t)/8$ with increasing values of γ .

Fig. 5. Comparison of Groupiness Factor Computed by Temporal Hilbert Filter and SIWEH for 40 NSA Simulations of JONSWAP Spectra.

Therefore, the SIWEH Groupiness Factor is a parameter that reflects the low pass filter characteristics used and the narrowness of the spectrum.

Figure 6 shows the wave height function estimated for a hurricane wave record from Wave Project 11 using the temporal Hilbert filter proposed by McGlellan et al. (1979) with $k = 95$. The values between the discrete times of the widely sampled envelope time series ($\Delta T = 3.2$ seconds) have been interpolated using an FFT numerical technique. As was noted by Medina and Hudspeth (1987), the wave height function contains

sufficient low frequency information from wave records using a minimum amount of data because the larger sampling interval ΔT has a high enough Nyquist frequency to retain the important information from the square wave height spectrum, $S_{H_2}(f)$.

Fig. 6. Wave Height Function for a Wave Project II Wave Record Sampled at $\Delta T = 3.2$ sec and Numerically Interpolated via FFT ($\eta(t)$ sampled at $\Delta t = 0.2$ sec).

LOCAL FREQUENCY FUNCTION

The local frequency function defined by Eq. (6) represents the instantaneous frequency of the orbital movement of a point in the sea surface.

The variable Ω is non-Gaussian, has a large kurtosis, and is centered about the mean frequency $f_{01} = m_1/m_0$. However, if the values of Ω corresponding to increasing levels of H are selected, the standard deviation of Ω decreases. These preliminary results from the analysis of numerically simulated waves indicate an inverse relation between the variance of Ω , $\sigma^2(\Omega)$, and the wave height function, $H(t)$. On the other hand, the observed mean frequency, $\bar{\Omega}$ is approximately $f_{01} = m_1/m_0$, and independent of the H level selected.

Longuet-Higgins (1975) extended the work of Rice (1954) to estimate the joint distribution between wave heights and wave periods assuming a narrow-banded process. This theoretical derivation used approximations for the derivative of the phase angle which are directly related to $\Omega(t)$. Considering the definition of $H(t)$ and $\Omega(t)$ in relation to the complex

envelope given by Longuet-Higgins (1975), the fluctuation of the orbital velocity, $v(t)$, may be defined as

$$v(t) = \pi H(t) [\Omega(t) - f_{01}] \quad (15)$$

For a narrow-banded process, the equations given by Rice (1954) and Longuet-Higgins (1975) can be transformed to estimate the joint probability density function of (H, v) according to

$$p(H, v) = \frac{H}{4m_0} \exp\left[-\frac{H^2}{8m_0}\right] \frac{1}{\sqrt{2\pi} \sigma_v} \exp\left[-\frac{v^2(t)}{2\sigma_v^2}\right] \quad (16)$$

where the variance of $v(t)$ is

$$\sigma_v^2 = (2\pi)^2 \nu^2 f_{01}^2 m_0 \quad (17)$$

where $\nu^2 = (m_2 m_0 / m_1^2 - 1)$, and the simplest stochastic model to describe jointly $[H(t), v(t)]$ is a stochastic process of two independent variables that are Rayleigh and Gaussian distributed, respectively.

The stochastic properties of $H(t)$ are described approximately by the spectra given by Eqs. (12) and (13) and by the exact Rayleigh distribution for the variable H . On the other hand, the stochastic properties of $v(t)$ can be defined independently of $H(t)$ by a Gaussian process with a variance approximated from Eq. (17).

The spectral density function of $v(t)$ for broad-banded spectra has been analyzed from DSA-FFT numerical simulations by comparing it with the spectra of $V(t)$ and $H(t)$ where

$$V(t) = \pi H(t) f_{01} + v(t) = V_0(t) + v(t) \quad (18)$$

where $V_0(t) = \pi H(t) f_{01}$ is the narrow-band approximation and $v(t)$ is a fluctuating orbital velocity.

$H(t), v(t)$, and spectral parameters have been calculated from a set of 40 DSA-FFT simulations of JONSWAP spectra with $\gamma = 1$ and $\gamma = 10$ ($f_p = 0.1$ Hz). The results obtained from these simulations indicate the following:

- The fluctuating orbital velocity, $v(t)$, is independent of the wave height function, $H(t)$.
- The variance of $v(t)$ [σ_v^2] is correctly given by Eq. (17) for narrow and wide spectra. However, if $v(t)$ is numerically calculated from a time series of the water surface elevation sampled with time interval Δt , the variance decreases when Δt increases ($\Delta\sigma_v^2 < 8\%$ if $\Delta t < 1/10 f_p$ and $\gamma < 10$).
- The spectrum of $v(t)$ has a positive maximum at zero frequency and is affected (as noted previously) by the Fourier transform of the temporal window Δt in numerical calculation of $v(n\Delta t)$. Sample $S_v(f)$ are approximately chi-squared distributed about the mean value with two degrees-of-freedom.

Figure 7 illustrates the mean spectra of $v(t)$ calculated numerically from a set of 40 DSA-FFT simulations of JONSWAP spectra ($\gamma = 1$ and 10, $f_p = 0.1$ Hz, $f_{max} = 4 f_p$, and $\Delta t = 0.5$ sec).

Fig. 7. Mean Spectrum of Fluctuating Orbital Velocity from 40 DSA-FFT Simulations of JONSWAP Spectra, $f_p = 0.1$ Hz and $\Delta t = 0.5$ sec ($\gamma = 1$ and 10).

Given the variance spectrum of the process, $S_v(f)$, a realization of $H(t)$ can be obtained using Eqs. (9), (12a) and (13). Using Eqs. (17) and (18) and spectra estimated in Fig. 7, it is possible to generate Gaussian time series of $v(t)$ independently from $H(t)$. The local frequency function can then be approximated by

$$\Omega(t) = f_{01} + \frac{v(t)}{\pi H(t)} \tag{19}$$

The first term of Eq. (19) represents the narrow-banded approximation and the second term represents the fluctuating component induced by spectral wideness. Note that the contribution from the second term decreases with increasing $H(t)$.

RUNS OF WAVES: THREE AXES REPRESENTATION

Assuming that successive upcrossings of $H(t)$ at a threshold level h are uncorrelated, Longuet-Higgins (1984) estimated the pdf of the length of runs based on the envelope to be given by the following:

$$p(2\ell_h) = \frac{1}{(2\bar{\ell}_h)} \exp \left[-\frac{2\ell_h}{2\bar{\ell}_h} \right] \tag{20}$$

$$p(1\ell_h) = \frac{1}{(1\bar{\ell}_h)} \exp \left[-\frac{1\ell_h}{1\bar{\ell}_h} \right] \tag{21}$$

$$\begin{pmatrix} 2 \\ 1 \end{pmatrix} \bar{\ell}_h = \exp \left[\frac{h^2}{8m_0} \right] \quad (22)$$

in which ${}_1\bar{\ell}_h$ and ${}_2\bar{\ell}_h$ = the length of run of high waves and total run of waves, respectively; $p(\cdot)$ = the probability density function, and h = threshold level. Run lengths calculated from both a succession of discrete waves and from the envelope could follow the exponential model because of the similarities found between the formulas given by Kimura (1980) for discrete waves and by Rice (1954) and by Longuet-Higgins (1984) for the envelope.

Three Axes Representation

Equations (20) and (21) demonstrate that the pdf of the length of runs of waves are controlled by the mean length of run at different levels. Therefore, the representation of these mean lengths of run of waves will characterize the statistical structure of wave groups. Longuet-Higgins (1984) gave the following estimation of the average length of run of high waves:

$${}_1\bar{\ell}_h = \frac{1/\delta}{\sqrt{4\pi} (h/\sqrt{8m_0})} \quad (23)$$

in which $\delta^2 = 1 - (m_1^2/m_0m_2) = \nu^2/(1+\nu^2)$. Equations (23) and (22) can be rewritten as

$$({}_1\bar{\ell}_h) = \exp[\alpha_0] / \left(\frac{h}{\sqrt{8m_0}} \right)^{\beta_0} \quad (24)$$

$$\begin{pmatrix} 2 \\ 1 \end{pmatrix} \bar{\ell}_h = \exp \left[\left(\frac{h}{\sqrt{8m_0}} \right)^{\beta_1} \exp(\alpha_1) \right] \quad (25)$$

where Eq. (24) is equivalent to Eq. (23) if $\beta_0 = 1$ and $\alpha_0 = -1/2 \ln(4\pi \delta^2)$ and Eq. (25) is equivalent to Eq. (22) if $\alpha_1 = 0$ and $\beta_1 = 2$.

Introducing the following change of variables:

$$u = \ln \left(\frac{h}{\sqrt{8m_0}} \right) ; \quad v = \ln({}_1\bar{\ell}_h) ; \quad w = \ln \left[\ln \left(\frac{{}_2\bar{\ell}_h}{{}_1\bar{\ell}_h} \right) \right] \quad (26a,b,c)$$

Equations (24) and (25) can be transformed into the following equations for straight lines:

$$w = \alpha_1 + \beta_1 u ; \quad v = \alpha_0 - \beta_0 u \quad (27a,b)$$

If the exponential approximation is valid, this permits a graphic representation in three axes of pairs of values $({}_1\bar{\ell}_h, {}_2\bar{\ell}_h)$ that should fit on

straight lines with $\alpha_1 = 0$, $\beta_1 = 2$, $\beta_0 = 1$ and α_0 depends on the spectral shape.

Figure 8 illustrates a three-axes representation of the mean length of waves observed from envelopes of 40 DSA-FFT simulations of JONSWAP spectra ($\gamma = 10$, $f_p = 0.1$ Hz, $f_{max} = 4 f_p$) sampled at intervals of $\Delta T = 0.5$ sec), and $\Delta T = T_{01}$. Also runs of discrete waves in the same simulations and observations of Goda (1983) of long-traveled swell waves are represented.

Fig. 8. Three-Axes Representation of Mean Length of Runs Estimated by Discrete Waves and by Envelope (40 DSA Simulations of JONSWAP Spectrum $\gamma = 10$, $f_p = 0.1$ Hz).

The exponential approximation agrees quite well (lines 'a', and 'b') using the envelope sampled at small time intervals. Although line 'b' seems quite robust (related to the Rayleigh distribution), line 'a' depends on the sampling time interval of the envelope; showing larger length of runs for a larger ΔT .

Figure 9 shows the mean length of runs obtained from simulations ($\gamma = 1$ and 10) and from analysis of discrete waves. The square of the wave height function, $H^2(t)$, has been filtered with a rectangular window of length T_{01} . The agreement depends on γ and demonstrates that the analysis of length of runs of waves using the envelope is far different from that using discrete waves. Neither sampling nor filtering $H(t)$ permit a comparison of these results.

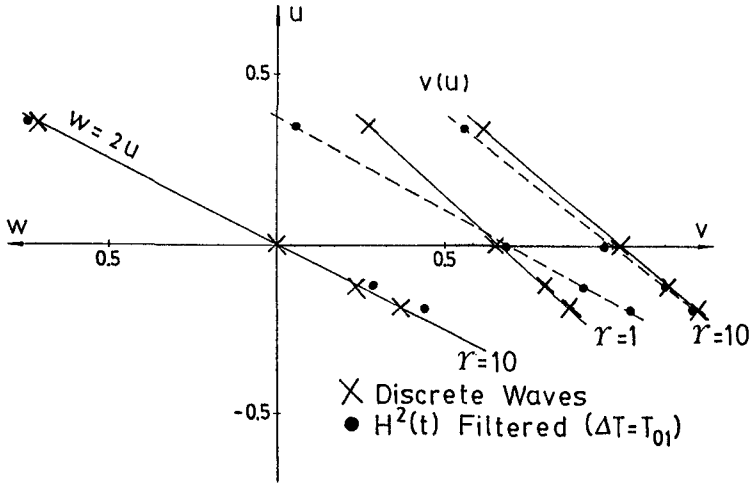

Fig. 9. Three-Axes Representation of Mean Length of Runs Estimated by Discrete Waves and by Temporal Hilbert Filter with a Rectangular Window $\Delta T = 1/f_{01}$ for JONSWAP Simulations ($\gamma = 1$ and 10 , $f_p = 0.1$ Hz).

CONCLUSIONS

Based on a linear assumption, and supported by observations of different authors in non-shallow waters, the analysis of waves in the complex plane leads to definitions of a wave height and a frequency which represent the instantaneous values of these variables for random seas. Efficient Hilbert filters in the time domain make it possible to define with reasonable precision the waves in the complex plane and to compare the results with other analyses.

The use of temporal Hilbert filters to estimate $H^2(t)/8$ is the best method to define the instantaneous variance function of a record. The isolation of the low frequency components of $\eta^2(t)$ by this methodology is better than the SIWEH and other empirical methods. The Groupiness Factor, GF, is not an efficient way to characterize wave grouping characteristics because of the amount of smoothing that is introduced in relatively broad-banded spectra.

The local frequency function $\Omega(t)$ can be defined on the basis of a mean value $f_{01} = m_1/m_0$ and a fluctuating component that is inversely proportional to the wave height function, $H(t)$.

A three-axes representation of mean length of runs of waves shows that neither sampling nor filtering $H(t)$ makes it possible to compare directly the results from analyzing a sequence of discrete waves with an analysis from the continuous wave height function.

CHAPTER 67

On the Methodology of Selecting Design Wave Height

Yoshimi Goda*, M. ASCE

ABSTRACT

A statistically-rational method of extreme wave data analysis is presented. A combination of the Fisher-Tippett type I and the four Weibull distributions is proposed as the candidates of distribution functions. The least square method is used for data fitting. The best plotting position formula for each function is determined by the Monte Carlo method with 10,000 simulations per sample size.

Confidence intervals of estimated extreme wave heights for given return periods are evaluated by simulations and expressed in the form of empirical formulas, for both the cases when the true distribution is known and unknown. An example of extreme wave data analysis is given.

1. INTRODUCTION

Design waves must be decided upon by the responsible engineer in charge of a maritime project. He looks for various data source on storm waves and asks statisticians to make extreme wave analysis. Based on the statistical estimate of wave height for a certain return period, he makes a final decision. The statistical procedure for this purpose is rather confused at present, however, with several different methods being employed in various occasions. Some procedure is not recommendable from the statistical point of view, and some other is quite complicated to use. There is a need for a clear and sound statistical method for extreme wave data analysis.

Another problem in extreme data analysis is the lack of information on the statistical uncertainty or confidence interval of estimated extreme value for a given return period (hereinafter called "return value" for the sake of simplicity). For the Fisher-Tippett type I distribution (abbreviated as FT-I), a formula is given in Gumbel's book (1958, Sec. 6.2.3). Lawless (1974) also gave integral form-

* Professor, Yokohama National University, Department of Civil Engineering, 156 Tokiwadai, Hodogaya-ku, Yokohama, Japan 240.

ulas for the FT-1 distribution for the case when the parameters are estimated by the maximum likelihood method. Both formulas are applicable for the annual maximum series data but inapplicable for the partial-duration series data. For the Weibull distribution, there is practically no formula available for the confidence interval of return values. The problem of confidence interval when the true distribution is unknown has only been mentioned by Petruaskas and Aagaard (1970), but they did not give any formula for its estimation.

The present paper tries to give a clear view of the practical procedure of extreme wave data analysis, which is statistically sound and easily applicable. The confidence interval of return values will also be estimated for several distribution functions used in the analysis. Detailed descriptions can be found in Goda (1988) in Japanese.

2. CLASSIFICATION OF EXTREME WAVE STATISTICS

Total Sample Method versus Peak Value Method

Two different methods are currently employed to prepare extreme statistics of storm waves. The first one may be called the total sample method which employs the all wave data recorded at a regular interval of a few hours. The second one may be called the peak value method which picks up the peak wave heights of individual storms and thus composes a set of extreme wave data.

The total sample method was proposed by Draper (1966), when wave observation projects at various countries were at their initial stages and the accumulation of wave data was short in terms of the time span of observation. This method is applicable even when the observation is a few years long and it is easy to use. However, the method violates the condition of statistical independence between individual data, because the regularly recorded wave heights are mutually correlated; the correlation coefficient remains over 0.3 to 0.5 with the time lag of 24 hours (see a review by Goda 1979). Therefore, use of the total sample method should be refrained in the present days when longer wave data by observations and/or hindcasting are available.

The total sample method also has an ambiguity in the selection of unit time in assessing return wave heights. One may take the recording interval of a few hours, but he may use one day as the unit time instead. Depending on the unit time, the return wave heights vary. Medina and Aguilar (1986) have proposed to employ the mean period between successive storms in their attempt to compromise the total sample method with the statistical condition of independent data.

Annual Maximum Series versus Partial-Duration Series

The data set for the peak value method can be either the annual maximum series or the partial-duration series. The latter refers to the series of peak storm wave heights in

the order of appearance. The annual maximum series data is clear in definition and easy to deal with. Most of wave data, however, cover rather short time spans, say less than 40 years by hindcasting and 10 years by instrumental observations. Therefore, the partial-duration series is the usual data source for extreme wave analysis.

In the analysis of partial-duration series data, the mean number of storm waves per year is an important parameter. It is called here as the **mean rate** and denoted with λ . The annual maximum series data can be treated as the case with $\lambda = 1$, although the meaning is slightly different. In practice of extreme wave analysis, the data above a certain threshold height are usually adopted to constitute the data set. Such data is called the **censored data** in contrast with the **uncensored data** which is composed of all storm wave data. The ratio of the number of adopted data N to the whole number of storm data N_T is hereby called the **censoring parameter** and denoted by ν : i.e., $\nu = N/N_T$. Burcharth (1988) calls the method utilizing the censored partial duration series data as the Peak-over-threshold method.

Methods of Data Fitting to Distribution Functions

There are four methods for fitting a set of extreme wave data to some distribution function. They are the graphical method, the method of moments, the least square method, and the maximum likelihood method. The graphical method is susceptible to subjective judgment and not recommended except for initial analysis. The moment method requires fewer calculation than the least square method, but cannot deal with the censored data. The maximum likelihood method is theoretically rigorous and favored by many statisticians, but the calculation is cumbersome even though the present computers can handle it with ease.

The least square method is a sophistication of the graphical method, but it has been neglected by most of statisticians except for a few such as Blom (1963) by reasons unknown. It is simple and clear in the calculation process, and therefore it is adopted in the present paper for extreme wave data analysis.

3. DISTRIBUTION FUNCTIONS AND PLOTTING POSITION FORMULAS

Candidates of Distribution Functions

In the extreme data analysis of various environmental phenomena such as rainfall, flood discharge, strong wind, and storm waves, selection of distribution functions to be fitted to the data is always a problem. No theoretical justification is provided for the selection except that the FT-I should be applicable if the basic population to define the maximum of a group of data belongs to the exponential distribution. In some occasion, a particular distribution such as the FT-I or the log-normal is assumed as applicable to the data set even without any theoretical support. In many occasions, however, several candidate functions are tested and the best fitting distribution is adopted.

Petruaskas and Aagaard (1970) have proposed to choose among a set of the FT-I and the seven Weibull distributions with the shape parameter fixed at certain values. As will be seen later, the capability of the extreme data analysis to recognize the parent distribution among several candidates is rather low when the sample size is less than 100 or so. Therefore, it is better to restrict the number of candidate distributions. The present paper proposes the following set of five functions:

FT-I distribution:

$$F(x) = \exp\{-\exp[-(x-B)/A]\} \quad (1)$$

Weibull distribution:

$$F(x) = 1 - \exp\{-(x-B)/A\}^k \quad (2)$$

$$: k = 0.75, 1.0, 1.4, \text{ and } 2.0$$

The distribution function $F(x)$ represents the probability of nonexceedance of the variate x , and A , B , and k are called the location, scale, and shape parameters, respectively. It is often useful in the extreme statistics to introduce the reduced variate y which is defined by

$$y = (x-B)/A \quad (3)$$

The log-normal distribution is not adopted here, because its characteristics are quite similar with those of the Weibull distribution with $k = 2.0$ and it requires the calculation of the error function, which is not easy to make with a pocket calculator.

Selection of Plotting Position Formulas

A drawback of the least square method for extreme data analysis is the necessity of choosing a right plotting position formula for each distribution function. Figure 1 is an example of the histograms of the ordered extreme data and its nonexceedance probability. The parent distribution is the FT-I ($A = 1.0$ and $B = 0$), and 100 samples with 10 data each are randomly drawn from the population. In each sample, the largest data $x_{(1)}$ are sorted out and its histogram is shown in the right. The nonexceedance probability F_1 corresponding to $x_{(1)}$ is shown in the top as a histogram.

The probability to be assigned to each ordered extreme data, which depends upon the ordered number and the total data number only, is called the plotting position. Cunnane (1978) has made a critical review of this problem and denounced the recommendation by Gumbel (1958) of the Weibull formula, which is expressed as

$$\hat{F}_m = 1 - m/(N + 1) \quad (4)$$

where m is the descending ordered number from the largest.

A plotting position formula should be so selected to

Fig. 1 Distribution of the largest data in a sample from FT-1.

Fig. 2 Mean bias of return values due to plotting formulas in Weibull distrib. ($k=1.0$).

Fig. 3 Mean bias of return values due to plotting formulas in FT-1 distribution.

Fig. 4 Example of return wave height estimation with various distribution functions.

yield no bias on the mean and the least root-mean-square error of the return values. The first choice would be the use of the probability corresponding to the expected value of the ordered variate, or $F\{E\{x_{(m)}\}\}$. Gringorten (1961) has derived the following formula for the FT-I distribution:

$$\text{FT-I: } \hat{F}_m = 1 - (m - 0.44)/(N_T + 0.12) \quad (5)$$

$$: m = 1, 2, \dots, N$$

in which N_T is the number of whole extreme data including those below a threshold value. Use of N_T instead of N (number of adopted data) is to enhance the possibility of recognizing the parent distribution for the case of censored data, after the suggestion by Muir and El-Shaarawi (1986). For the Weibull distribution, Petruaskas and Aagaard (1970) have presented the following formula:

$$\text{Weibull: } \hat{F}_m = 1 - (m - \alpha)/(N_T + \beta) \quad (6)$$

where

$$\alpha = 0.30 + 0.18/k, \quad \beta = 0.21 + 0.32/k \quad (7)$$

Figure 2 shows the bias of return values caused by use of various plotting position formulas for the case of FT-I distribution. The sample size is varied from 10 to 300, and 10,000 uncensored samples are simulated by the Monte Carlo method at each sample size. The bias is defined here as $100 \times (\hat{x}_R/x_R - 1)$, where \hat{x}_R and x_R refer to the estimated and true return values, respectively. The return values are evaluated at the return period being 10N.

It is clear in Fig. 2 that the Weibull formula yields conspicuous positive bias, indicating a tendency of over-estimation. The formula by Barnett (1975) though not presented here gives practically no bias just as same as Gringorten's formula. The formula denoted as "New" has the expression same as Eq. 6 but with the constants $\alpha = 0.51$ and $\beta = 0.18$. This formula has been derived as to yield the best fitting to $F\{E\{x_m\}\}$, but it yields slightly negative bias. Figure 2 clearly indicates the Gringorten formula to be used for the FT-I distribution. Poor performance of the Weibull formula has also been reported by Carter and Challenor (1983) with a small scale Monte Carlo simulation, in which they compared the effectiveness of various methods of extreme data analysis.

Figure 3 shows a similar comparison of plotting position formulas for the Weibull distribution with $k = 1.0$. The Weibull formula again exhibits large positive bias. The formula by Petruaskas and Aagaard (denoted as "P & A") shows a tendency to yield slightly negative bias. A modification is made here by changing the constants as

$$\alpha = 0.20 + 0.27/\sqrt{k}, \quad \beta = 0.20 + 0.23/\sqrt{k} \quad (8)$$

The new formula is denoted as "New P & A" in Fig. 3. This plotting formula is used in this paper hereinafter.

For the log-normal distribution, the appropriate plotting position formula is that by Blom (1958) in the form of Eq. 6 with $\alpha = 3/8$ and $\beta = 1/4$. Use of the Weibull formula yields positive bias as demonstrated in a simulation study by Earle and Baer (1982). The amount of bias reported by them has been confirmed in the author's simulation (Goda, 1988); use of the Blom formula for the same condition has yielded no bias.

4. DATA FITTING AND CALCULATION OF RETURN VALUES

For a given set of extreme wave data, the first step of data processing is to rearrange the data in the descending order from the largest to the smallest. Then the nonexceedance probability \hat{F}_m is assigned to each data by Eqs. 5, 6, and 8 by assuming the FT-I and the four Weibull distributions as the candidate functions. For each \hat{F}_m , the following reduced variate $y_{(m)}$ is then calculated:

$$\text{FT-I:} \quad y_{(m)} = -\ln[-\ln \hat{F}_m] \quad (9)$$

$$\text{Weibull:} \quad y_{(m)} = [-\ln(1 - \hat{F}_m)]^{1/k} \quad (10)$$

Because there should exist a linear relation between the ordered variate $x_{(m)}$ and its reduced variate $y_{(m)}$, the following equation is assumed and solved by the least square method to yield the estimates \hat{A} and \hat{B} of the scale and location parameters:

$$x_{(m)} = \hat{A} y_{(m)} + \hat{B} \quad (11)$$

Table 1 is an example of the above procedures applied for an extreme data of typhoon waves measured at the depth of 50 m at a location facing the Pacific. The measurement has been continued for more than 15 years, and the portion of successful recording covering $K = 10.74$ years is used in the analysis. There were 53 typhoon waves during this effective observation period of 10.74 years, and thus $N = 53$ and $\lambda = 4.93$ per year. The wave heights exceeding 4.0 m have been chosen for the analysis, and there were 21 such data; i.e., $N = 21$ and $\nu = 0.396$.

The nonexceedance probabilities \hat{F}_m listed in Table 1 are all above 0.61, because the total number of typhoon waves $N_T = 53$ is used in evaluating \hat{F}_m by Eqs. 5 and 6. Even if the threshold height is changed to 4.5 m and the number of data is reduced to $N = 18$, the probability \hat{F}_m remains at the same value so long as N_T is the same.

The return value or the expected extreme wave height for a given return period R is then calculated by the following equation with the estimated parameters \hat{A} and \hat{B} :

$$x_R = \hat{A} y_R + \hat{B} \quad (12)$$

where

$$\left. \begin{aligned} y_R &= -\ln[-\ln(1 - 1/(\lambda R))] && : \text{FT-I} \\ y_R &= [\ln(\lambda R)]^{1/k} && : \text{Weibull} \end{aligned} \right\} \quad (13)$$

Table 1. Example of Extreme Wave Data Fitting to Several Distribution Functions [units in meters]
 - N = 21, N_T = 53, K = 10.7 years -

$\bar{x} = 5.565$		A = 1.091		A = 0.614		A = 1.147		A = 2.084		A = 3.560	
$\sigma_x = 1.101$		B = 3.617		B = 4.029		B = 3.374		B = 2.334		B = 0.786	
		r = 0.9842		r = 0.9621		r = 0.9790		r = 0.9878		r = 0.9910	

Figure 4 exhibits the result of estimating the return wave heights for the data of Table 1. Depending on the distribution functions fitted to the data, the return wave heights vary and the difference increases as the estimate is made to longer return periods.

There is no absolute criterion to choose a particular function among several candidates fitted to an extreme data. For practical purposes, the correlation coefficient r between the ordered variate x_(m) and its reduced variate y_(m) can serve as the basis of selection. In the example of Table 1, the Weibull distribution with k = 2.0 indicates the highest correlation with r = 0.9910 and is chosen as the distribution best fitted to the data.

5. STANDARD DEVIATION OF RETURN VALUE WHEN THE TRUE DISTRIBUTION IS KNOWN

A set of extreme wave data being analyzed is regarded as a sample drawn from an unknown population of storm waves. Another set of extreme waves to be obtained in the coming several tens of years will form a sample different from the present sample, even if no long-term climatic change exists. The two sets of extreme data will surely yield different distribution functions and the return wave heights will eventually be different.

Figure 5 shows some results on the statistical variability of return values. A population with the FT-I distribution (A = 1 and B = 5) is assumed, and Monte Carlo simula-

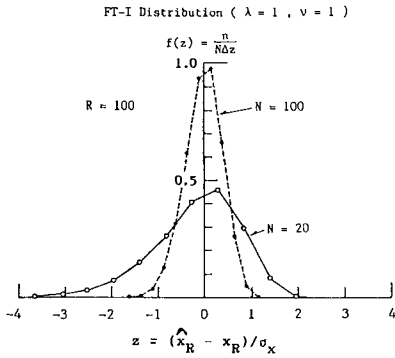

Fig. 5 Distribution of estimated return values in dimensionless form.

Fig. 6 Example of standard deviation of return values in censored samples from FT-I.

Fig. 7 Relative frequencies of best-fitted distributions for random samples.

Fig. 8 Example of standard error of return values when the true distribution is unknown.

tions are carried out to yield 10,000 uncensored samples each for the sample size $N = N_T = 20$ and 100. By fitting the FT-I function to each sample, the return value at the return period $R = 100$ is estimated. The difference between the estimated and true return value is normalized with the standard deviation of each sample σ_x . Figure 5 presents the histograms of this normalized deviation in the form of probability density. As seen clearly, the deviation may exceed $2\sigma_x$ in case of the sample with $N = 20$ and $1\sigma_x$ for $N = 100$.

Monte Carlo simulations have been carried out for various combinations of the distribution functions, the sample size, and the censoring parameter, in order to obtain sufficient data on the statistical variability of the return values. For each combination, the standard deviation of the dimensionless variate $z = (\hat{x}_R - x_R) / \sigma_x$ has been evaluated. Figure 6 is an example of the standard deviation σ_z multiplied by \sqrt{N} in order to reduce the influence of the sample size on data presentation. The data are those of censored ones ($v = 0.25$) sampled from the FT-I distribution.

Empirical formulations of the standard deviations of the return values have been tried by referring to the formula cited by Gumbel (1958) as in the following form:

$$\sigma_z = [1.0 + a (y_R - c + \epsilon \ln v)^2]^{1/2} / \sqrt{N} \quad (14)$$

where

$$a = a_1 \exp[a_2 N^{-1.3} + \kappa (-\ln v)^{1/2}] \quad (15)$$

The coefficients in the above equations are assigned the values listed in Table 2. The dashed and dotted curves in Fig. 6 represent the empirical predictions of the standard deviations of the return values.

Table 2. Coefficients of Empirical Formulas for Standard Deviation of Return Values When the True Distribution Is Known

Distribution	a_1	a_2	κ	c	ϵ
FT-I	0.84	9.0	0.93	0.0	1.33
Weibull (k=0.75)	1.65	11.4	-0.63	0.0	1.15
Weibull (k=1.0)	1.92	11.4	0.00	0.3	0.90
Weibull (k=1.4)	2.05	11.4	0.69	0.4	0.72
Weibull (k=2.0)	2.24	11.4	1.34	0.5	0.54

Once the dimensionless deviation σ_z is evaluated, the standard deviation of the return value can be approximately estimated as $\sigma(\hat{x}_R) = \sigma_z \sigma_x$. The confidence interval of the return value is then constructed with $\sigma(\hat{x}_R)$.

6. PROBLEM OF FINDING TRUE DISTRIBUTION

The capability of finding out the true distribution from a random sample of extreme data has been tested with Monte Carlo simulations. Figure 7 demonstrates some results. A parent distribution is assumed, and 10,000 uncensored random samples with the size 10 and 100 were prepared. For

each sample, a group of nine candidate distributions were applied and the best fitting one was selected by the criterion of the largest correlation coefficient between $x_{(m)}$ and $y_{(m)}$. The ordinates in Fig. 7 shows the relative frequency of the best-fitted function, while the abscissa stands for the distribution functions: $k = 0.75$ to 2.0 denote the Weibull distributions and "L-N" stands for the log-normal distribution. The set of Weibull distributions is same as that used by Petruaskas and Aagaard (1970).

It is clear in Fig. 7 that a small sample has only a small chance of selecting the parent distribution as the best-fitting one. Even at the sample size $N = 100$, samples from the FT-I distribution can be mistaken as those belonging to the log-normal distribution. Such competitive power of the log-normal against the FT-I and the Weibull distributions is one reason for the rejection of the former from the candidates of the distributions functions in the present proposal of extreme data analysis.

The low capability of a statistical data analysis in recognizing the true distribution function is due to the statistical variability of random samples. The standard deviation of an uncensored sample with the size 40 from the Weibull distribution ($k = 1.0$), for example, can be less than 0.5 times or more than 1.7 times the population value. A sample with a small deviation tends to be better fitted by the distribution with narrower spreading, and vice versa. Use of the statistical method other than the least square method may slightly enhance the capability of recognizing the true distribution, but the amount of enhancement will be small.

7. BIAS CORRECTION TO RETURN VALUE WHEN THE TRUE DISTRIBUTION IS UNKNOWN

Fitting of an extreme data to a distribution other than the true one causes a certain bias to the estimated return values, even though the right plotting position formula is employed. For example, if a sample from the Weibull with $k = 1.0$ is judged to be best fitted to the Weibull with $k = 0.75$, the return values will be overestimated because of the latter's characteristic of having a longer tail.

An attempt for the correction of this kind of bias is made in this paper, by assuming the five candidate distributions have the equal probability of existence in the nature. Another series of Monte Carlo simulations have been made with 2,000 to 10,000 samples for each combination of the parent distribution, sample size, and censoring parameter. Each sample is analyzed with the procedure described in this paper, and the return values are estimated and compared with the true values. The difference is normalized as $z = (\hat{x}_R - x_R) / \sigma_x$ and its ensemble mean is calculated for each distribution function which is best fitted to samples taken from various parent distribution functions. The ensemble mean of the dimensionless difference \bar{z}_n is thought to represent the bias due to not-knowing true distribution and is empirically formulated as in the following:

Table 3. Example of the Estimation of Return Wave Heights with Bias Correction and Their Standard Errors

Return Period (years)	FT-I		Weibull(0.75)		Weibull(1.0)		Weibull(1.4)		Weibull(2.0)	
	H _R (m)	σ (H) (m)	H _R (m)	σ (H) (m)	H _R (m)	σ (H) (m)	H _R (m)	σ (H) (m)	H _R (m)	σ (H) (m)
2.0	6.2	0.4	5.9	0.3	6.0	0.4	6.2	0.5	6.4	0.5
5.0	7.3	0.7	6.8	0.5	7.1	0.6	7.3	0.7	7.6	0.8
10.0	8.1	0.9	7.6	0.7	7.9	0.8	8.1	0.9	8.4	1.0
20.0	8.9	1.2	8.3	1.0	8.8	1.1	8.9	1.2	9.3	1.3
50.0	10.0	1.6	9.4	1.4	9.9	1.5	10.0	1.5	10.4	1.7
100.0	10.8	1.9	10.1	1.6	10.7	1.8	10.6	1.9	11.2	2.1

$$\bar{Z}_n = \begin{cases} A_c (y_R + \alpha \ln \nu)^p & : y_R > -\alpha \ln \nu \\ 0 & : y_R \leq -\alpha \ln \nu \end{cases} \quad (16)$$

The coefficients A_c and α and the exponent p are assigned the following values depending on the distribution functions and the censoring parameter:

FT-I :

$$\left. \begin{aligned} \nu &= 1.0 ; \\ A_c &= \begin{cases} 0.046 - 0.40[\log_{10}(60/N)]^3 & : N < 60 \\ 0.046 \exp\{-2.5[\log_{10}(N/60)]^2\} & : N \geq 60 \end{cases} \\ \alpha &= 0.9, \quad p = 1.0 \end{aligned} \right\} \quad (17)$$

$$\left. \begin{aligned} \nu &= 0.5 \text{ \& \ } 0.25 ; \\ A_c &= 0.01 - 0.044[\log_{10}(N/300)]^4 \\ \alpha &= 0.9, \quad p = 1.0 \end{aligned} \right\} \quad (18)$$

Weibull (k = 0.75) :

$$\left. \begin{aligned} A_c &= \begin{cases} 0.030 \exp\{-0.6[\log_{10}(N/4)]^2\} & : \nu = 1.0 \\ 0.025 \exp\{-0.7[\log_{10}(N/15)]^2\} & : \nu = 0.5 \text{ \& \ } 0.25 \end{cases} \\ \alpha &= 2.7, \quad p = 1.6 \end{aligned} \right\} \quad (19)$$

Weibull (k = 1.0) :

$$\left. \begin{aligned} A_c &= \begin{cases} -0.028 N^{-0.25} & : \nu = 1.0 \\ -0.0022 - 0.0006[\log_{10}(N/50)]^2 & : \nu = 0.5 \text{ \& \ } 0.25 \end{cases} \\ \alpha &= 1.0, \quad p = 2.1 \end{aligned} \right\} \quad (20)$$

Weibull (k = 1.4) :

$$\left. \begin{aligned} A_c &= \begin{cases} -0.40 N^{-0.8} & : \nu = 1.0 \\ -0.10 N^{-0.4} & : \nu = 0.5 \text{ \& \ } 0.25 \end{cases} \\ \alpha &= 0.5, \quad p = 2.7 \end{aligned} \right\} \quad (21)$$

Weibull (k = 2.0) :

$$\left. \begin{aligned} A_c &= \begin{cases} -0.50 N^{-0.7} & : \nu = 1.0 \\ -0.64 N^{-0.6} & : \nu = 0.5 \text{ \& \ } 0.25 \end{cases} \\ \alpha &= 0.35, \quad p = 3.4 \end{aligned} \right\} \quad (22)$$

The bias correction can be made by using \bar{Z}_n as

$$(x_R)_{cor} = \hat{x}_R - \bar{Z}_n \sigma_x \quad (23)$$

Table 3 lists the return wave heights with bias correction for the data of Table 1. The bias correction by the

above formula may have been excessive, being judged from the fact that the Weibull distribution with $k = 2.0$ predicts the largest return heights after bias correction. This is due to the assumption of the equal probability of the five distribution employed. A responsible engineer may adjust the amount of bias correction in his selection of design waves.

8. STANDARD ERROR OF RETURN VALUE WHEN THE TRUE DISTRIBUTION IS UNKNOWN

When the true distribution is unknown, the standard error of the estimated return value differs from the standard deviation formulated as in the form of Eq. 14. By using the simulation data for the above bias correction, empirical formulation has been made for the standard error of return value with bias correction. The standard error is defined as $\bar{S}_n = \sigma [(\hat{x}_R - x_R)/\sigma_x]$ and is formulated as

$$\bar{S}_n = \{1.0 + A_s |y_R + \alpha \ln v|^p\} / \sqrt{N} \quad (24)$$

The coefficient A_s is expressed as below,

$$A_s = b_1 + b_2 [\log_{10} (N/N_c)]^2 \quad (25)$$

and the coefficients α , b_1 , b_2 , and N_c and the exponent p are assigned the values as in Table 4: α is common with Eqs. 16 to 22. An example of the comparison between the simulation data and empirical formula is shown in Fig. 8.

Table 4. Coefficients of Empirical Formulas of Standard Error of Return Values when the True Distribution Is Unknown

Distribution	ν	b_1	b_2	N_c	p	ϵ
FT-I	1.0	0.24	0.36	80	1.6	0.9
	0.5, 0.25	0.46	0.14	50	1.6	0.9
Weibull (k=0.75)	1.0	0.57	0.18	20	1.2	2.7
	0.5, 0.25	0.41	0.22	20	1.2	2.7
Weibull (k=1.0)	1.0	0.55	0.15	15	1.7	1.0
	0.5, 0.25	0.38	0.17	20	1.7	1.0
Weibull (k=1.4)	1.0	0.37	0.08	1000	2.3	0.5
	0.5, 0.25	0.46	0.09	20	2.3	0.5
Weibull (k=2.0)	1.0	0.30	0.36	80	3.2	0.35
	0.5, 0.25	0.56	0.20	100	3.2	0.35

The absolute magnitude of the standard error can be estimated as $\sigma(\hat{x}_R) = \bar{S}_n \sigma_x$. The columns of $\sigma(H)$ in Table 3 list the estimated standard errors of return wave heights for the extreme wave data listed in Table 1. By taking the one-sigma or two-sigma criterion, one can easily construct the confidence interval of the return wave heights.

9. PROBLEM OF MULTI-POPULATIONS

Any statistical data analysis must satisfy the condition of homogeneity: i.e., all the data under analysis should belong to the same population. Extreme waves are generated by hurricanes, monsoons, frontal systems, and others. Strictly speaking, these meteorological disturb-

ances create different populations of storm waves and they should be analyzed separately. Resio (1978), for example, demonstrated the necessity of separate analysis of extreme waves off Cleveland in Lake Erie. Carter and Challenor (1981) also discussed the effect of seasonal variations of wind speeds and wave heights on the estimation of their return values.

Separation of extreme waves according to their generating sources is feasible and the extreme data analysis can be made for each type of storm waves. For each population data, the best distribution function is fitted and the return wave height is estimated separately. To estimate the overall return value, the method by Carter and Challenor (1981) can be modified as follows. First, the distribution function for the partial-duration series data is converted to that corresponding to annual maximum series data by assuming the Poisson distribution. Then, the overall distribution function is evaluated as the product of all the individual distribution functions. Thus,

$$\begin{aligned} F(x) &= \prod_{j=1}^n \exp\{-\lambda_j [1 - F_j(x)]\} \\ &= \exp\left\{-\sum_{j=1}^n \lambda_j [1 - F_j(x)]\right\} \end{aligned} \quad (26)$$

where n denotes the number of populations, and λ_j and F_j are the mean rate and the best-fitted distribution function of the j -th population, respectively. The overall distribution function thus evaluated represents the nonexceedance probability of annual maximum wave height. The return wave height for the return period R is numerically evaluated as the height corresponding to the probability of $F = 1 - 1/R$.

10. CONCLUDING REMARKS

The present paper is essentially an extension of the work by Petruaskas and Aagaard (1970). The plotting position formulas have been examined and modified. The number of candidate distribution functions is reduced from eight to five, in recognition of low capability of the extreme data analysis in separating the true distribution from other candidates. The magnitude of errors owing to not-knowing the true distribution is estimated in terms of both the bias and the standard deviation. Empirical formulations are presented to estimate the amounts of bias and standard error of return wave heights.

It should be emphasized that any estimation of return value is accompanied by the statistical variability due to sampling error. In other words, an extreme wave data under analysis is but a sample taken from an unknown population of storm waves. Depending on the characteristics of a particular sample relative to those of population, the result of extreme data analysis might be an overestimate or an underestimate compared with the population value,

which remains unknown. A responsible engineer should take this uncertainty into account when he has to make selection of design waves. The formula of standard error presented as Eq. 24 would serve as a guide to measure the magnitude of uncertainty.

The uncertainty of return wave height can only be reduced through the increase of the time span of wave observation or wave hindcasting. Sampling of many storms as much as possible within a given time span is also helpful in reducing the amount of standard error of return wave height. In this sense, further continuous efforts of instrumental wave observations of longer duration should be encouraged.

CHAPTER 68

UNSTEADY FLOW AROUND A VERTICAL CIRCULAR CYLINDER IN A WAVE

Kenjiro Hayashi*
and
Toshiyuki Shigemura**

ABSTRACT

The unsteady characteristics of flow around a vertical circular cylinder in a typical wave, under which the lift force acting on it is very stable and has a frequency which is twice that of the incident wave, have been investigated experimentally. The relationship between the fluctuating flow velocities near the boundary layer separation points and the lift force acting on a sectional part of the cylinder has been understood quantitatively. To clarify the region where the appearance of stable lift force occurs, the long time records of lift forces acting on vertical cylinders in waves are also performed.

1. INTRODUCTION

In order to develop the study of wave forces acting on the offshore structures, it is important to understand the flow around a vertical circular cylinder in waves. The principal phenomenon of this flow is characterized by the formation of vortices which are shed from the surface of a cylinder. However, it is not understood so well as those in steady flow. This may be due to the complexity of flow round a vertical cylinder in waves, because the incident fluid motion varies along the axis of vertical cylinder with possessing a vertical velocity component. A lot of experimental works remain to be made in these area.

When the wave depth parameter d/L (d =depth of mean water level, L =wave length) is small, shallow water wave, the variation of incident flow with depth is small and the amplitude of vertical velocity component is small compare with that of horizontal velocity component. Therefore, the flow around a vertical cylinder is nearly two dimensional and quite similar to those in harmonically oscillating two dimensional flow, plane oscillatory flow. On the other hand, when the wave depth parameter d/L is large, deep water wave, the flow around a vertical cylinder is three dimensional

* Assistant Professor, Dept. of Civil Engineering, National Defense Academy, 1-10-20 Hashirimizu Yokosuka, 239 Japan.

** Professor, Dept. of Civil Engineering, National Defense Academy, M. ASCE.

because the variation of incident flow along the axis of cylinder is large and the amplitude of vertical velocity component is nearly equal to that of horizontal velocity component.

Many studies have been made to understand the process of vortex shedding from a cylinder in these oscillating flow, plane oscillatory flow and wave, since the original work of Keulegan and Carpenter(1958). They observed the vortex formation round a submerged horizontal cylinder placed in harmonically oscillating flow produces in the node of standing waves and found a close relationship between the vortex-shedding frequency and a Keulegan-Carpenter number defined as $KC=U_m.T/D$ in which U_m is the maximum horizontal water particle velocity during a wave period T and D is a diameter of cylinder.

The relationship between the vortex-shedding patterns and KC number has been obtained by the visualization studies of the flow round a cylinder in waves and in plane oscillatory flow, see for example Bidde(1971) and Bearman(1979). Williamson(1985) made simultaneous force measurement and visualization round a cylinder in plane oscillatory flow by oscillating a cylinder in still water and obtained the detailed description of vortex shedding and the relation of the vortex motions to the lift force profiles in each regime of KC number corresponding to each of vortex shedding pattern.

In order to understand quantitatively the characteristics of flow round a cylinder in these oscillatory flow, the measurements of flow velocities round a cylinder and surface wave pressure on the circumference of a cylinder in waves have been made by Isaacson and Maull(1976), Iwagaki and Ishida(1976), Hayashi and Takenouchi(1980, 1985), Bearman et al.(1985) and Grass et al.(1987).

Hayashi and Takenouchi(1980,1985) measured the horizontal velocity around a vertical cylinder in a wave and the surface wave pressure on the circumference of it by using a Laser-Doppler anemometer and a pressure transducer. These measurements were made in a special flow condition under which the total lift force acting on the cylinder is very stable for a long time with having a frequency which is twice that of incident wave and major portion of vortex shedding and formation take place periodically on mainly one side of the cylinder. The vortex shedding pattern observed was quite similar to those generally observed in waves and in plane oscillatory flow in the approximate range of KC between 7 to 15. The characteristics of time variation and the phase average distributions of both the horizontal flow velocities and the surface wave pressures have been obtained.

Grass et al.(1987) also measured the velocity around a cylinder in waves and in plane oscillatory flow. They find the presence of vortex induced velocity enhancement effect occurring in the flow field round a cylinder both in plain oscillatory flow and in surface waves in the approximate

range of KC between 9 to 12. This velocity enhancement effect is also identified in the results of Hayashi and Takenouchi(1980,1985).

The study described herein is an extension of our study described above, Hayashi and Takenouchi(1979, 1985), clarifying the relationship between the flow around a vertical circular in waves and the forces acting on it. The scope of present study is to investigate the relationship between the flow near the boundary layer separation points and the lift force acting on a sectional part of the cylinder in a wave. The flow near a separation point of boundary layer has an important aspect of vortex shedding phenomenon. However, detail experimental information is scarce in the case of oscillatory flow. In order to clarify the region where the appearance of stable lift force occurs, the long time records of lift forces acting on the vertical circular cylinders in waves were also performed.

2. EXPERIMENTS

2.1 Measurement of Flow Velocity and Surface Wave Pressure

The detailed description of the experimental arrangement used in these measurements has been given previously in our study, Hayashi and Takenouchi(1980,1985). The experiments were carried out in the 39.6m long flume of the Department of Civil Engineering at the National Defense Academy. This flume is 0.6m wide and is equipped with a ballistic-pendulum type wave generator. A long beach with a slope of 1:6.7 is installed at the other end of flume to absorb the wave energy.

Fig.1 General arrangement of test cylinder

The general arrangement of a test cylinder made of acrylic plastic tube is shown in Fig.1. It was mounted in the flume at a section 24.6m from the paddle of wave generator and 7m from the toe of long beach. For the measurement of the total inline force F_x and total lift force F_y acting on a test cylinder, the upper end of the test cylinder was attached to a load cell(Three Component Strain Gauge Type Load Cell, LMC-3501-1 Nissho Ltd.) which was mounted on a two-dimensional traversing device straddling on the wave flume.

For the measurement of the fluctuating surface wave pressure P on the circumference of the test cylinder at the level of 19cm below the still water level, a diaphragm type pressure transducer(PM10-01, ST Institute Co.) was attached to a pressure tapping placed on a surface of the test cylinder. The test cylinder was attached to the load cell, so arranged that it can be rotated around its axis to bring the pressure tapping to any desired orientation.

The measurements of fluctuating horizontal water particle velocity U , the velocity component in the direction of wave propagation, at the points along a diameter through the cylinder parallel to the wave crest were made by using a laser doppler anemometer(LDA) of a 15mw He-Ne type(Kanomax 27-0900 ser.) and a hot wire anemometer. These velocity measurements were made at the level of 16cm below the still water level. The general view of optical system of LDA working in a forward scatter dual beam mode is shown in Fig.2. In order to eliminate an ambiguity of flow direction when flow reverses under wave motion, the frequency sifter was used in this LDA system.

Fig.2 Optical system of laser doppler anemometer

These measurements described above were made in a regular wave; wave period $T=1.6$ sec., wave height $H=10$ cm, wave length $L=2.9$ m, and still water depth $d=40$ cm, which is the same used in our previous work, Hayashi and Takenouchi(1980,1985). The

wave depth parameter d/L is about 0.138. The KC numbers at water surface and at the bottom of flume are 12.5 and 8.2 respectively, i.e. the variation of incident flow with depth is small. The KC number and the Reynolds number at the level of 15cm below the still water level are about 10 and 7700 respectively. The flow pattern around the test cylinder near the level of the measuring points U and P, about 16cm below the still water level, was observed by using a video recorder camera. Aluminum powder was spread in water.

Fig.3 Coordinate system

The coordinate system is shown in Fig.3. The measurement of surface wave pressure P was made at 19cm below the still water level and at 24 angular positions θ by rotating the cylinder at 15 degrees interval around its center axis. The signal of the pressure transducer at each angular point θ was recorded on the magnetic tape recorder simultaneously with the signals of wave gauge and the load cell for a total of about 5 wave periods. Using these data, it is possible to obtain the phase average surface wave pressure distribution circumference of the test cylinder and the phase average sectional inline and transverse forces over 5 wave periods for several wave phase t/T .

The measurements of velocity U were made at the level of 16.5cm below the still water level and at $X=0$ cm by varying Y from -7cm to 8cm. Instead of traversing the measuring points of velocity, the test cylinder was moved in the direction of Y coordinate. The signals from velocity meters were also recorded on the magnetic tape recorder with the signals from the wave gauge, the load cell and the pressure transducer for the total of 5 wave cycles and subsequently analyzed by a signal analyzer. Using this recording method, it is possible to obtain the relationship between the fluctuating velocity U and both the surface pressure P and wave forces F_x and F_y .

2.2 Long Time Measurement of Lift Forces

The long time measurements of lift forces were carried out by using a same facility described above. Two circular cylinders made of acrylic plastic tubes were mounted on a load cell as shown in Fig.1. They were 3cm and 4cm in diameter and 60cm in length. In order to eliminate the end effect, the clearance between the lower end of test cylinders and the bottom of wave flume was kept less than

1mm. Test runs were made at wave period T ranging from 0.8sec. to 2.2sec. At each wave period approximately 4 to 10 wave heights H were generated. The still water depth d was kept at 40cm. The approximate range of rms.KC number and rms.Re number were from 1 to 24 and 200 and 2200. The natural frequency of the test cylinders in still water were 12Hz for $D=3\text{cm}$ and 10Hz for $D=4\text{cm}$ respectively. The analog signals from the load cell and the wave gage were recorded on a magnetic tape recorder over a time interval about 800 wave periods.

3. RESULTS AND DISCUSSION

The record of the time variation of the total lift force F_y obtained from the experiment of flow velocity and wave pressure is shown in Fig.4. As shown in this figure, the time variation of F_y is very stable for a long time.

Fig.4 Long time variation of amplitude of lift force

Fig.5 Time variation of lift forces for several rms.kC

The time history of lift force acting on a vertical cylinder in waves has generally irregular characteristics of intermittency and modulation of its amplitude as shown in Fig.5, which is reproduced from a reference, Hayashi and Takenouchi(1979). These irregular characteristics may be due to the sensitivity of lift force to the stream turbulence and poor spanwise correlation of vortex shedding along a cylinder's axis. However, we can recognize the appearance of stable lift force as shown in Fig.4 in this figure, for the case of $\text{rms.KC}=11.8$.

In the case of plane oscillatory flow, it is recognized that the stable lift force appears in the range of KC approximately between 7 to 16 and in this range of KC, the vortex shedding is very stable with taking place on only one side of cylinder, see for example Maull and Milliner(1978), Ikeda and Yamamoto(1981), Williamson(1985) and Grass et al. (1987). The region of stable lift force in waves may be also represented in KC numbers which are related to the case of plane oscillatory flow. However, we should note that there are important differences between the unsteady natures of flow in waves and those in plane oscillatory flow as described previously in introduction.

Fig.6 Region of stable lift forces plotted against d/L and rms.KC

The relationship between the configuration of time history of lift forces, which were obtained in the present experiments, and both rms.KC and d/L is shown in Fig.6. In this figure, the black symbols show the appearance of stable lift force. The region of stable lift force for the case of

plane oscillatory flow obtained by Ikeda and Yamamoto(1981) are also shown in this figure. The quantity of present data is not sufficient to define exactly the region of stable lift force acting on a vertical cylinder in waves. This figure shows that the stable lift force occurs in the range of rms.KC between about 9 to 16, for the range of d/L between about 0.1 to 0.2. For the high value of d/L > 0.2, the stable lift force does not appear. This may be due to the fact that the vortex shedding is poorly correlated along the axis of the test cylinder, because the variation of incident flow along the cylinder axis increases with the increase of d/L. For the low value of d/L < 0.1, the stable lift force also does not appear. This may be due to the increased influence of wave nonlinearity.

While farther dependence of the stable lift forces in waves on Reynolds number is possible as mentioned by Maull and Milliner(1978) and Ikeda and Yamamoto(1981), such dependence is not clear in the present data.

Fig.7 Time variations of lift force F_y , inline force F_x , and free surface elevation η with vortex shedding patterns

In the present experiment of flow velocity U and surface wave pressure P , the time variation of lift force F_y is very stable for a long time as shown in Fig.6. The relationship between this F_y , and inline force F_x and water surface elevation θ with time are shown in Fig.7. The frequency of F_y is two times as much as those of F_x and η .

The process of vortex shedding in a period of incident wave is also shown in Fig.7. These sketches of vortex shedding patterns were estimated from the observation of flow near the level of velocity measurement U and surface wave pressure P , which were made by using a video camera in the present work, and the velocity distributions around a

vertical cylinder in waves which were obtained for several wave phases in our previous study by the author(1980,1985). The major portion of vortex shedding and its activity, which occur during each half cycle, take place periodically on only one side of the cylinder, negative side of Y coordinate. These are quite similar to those generally observed in plane oscillatory flow in the range of KC between about 7 to 13, which has been described in detail by Williamson(1985) and Grass et al.(1987).

Fig.8 Out put signals of velocities U and water surface elevation η

Time variations of horizontal water particle velocity U at various Y points of $X=0\text{cm}$, which were obtained by using the LDA, are demonstrated in Fig.8 (a),(b) and (c) respectively. To show the phase of incident wave, the time variation of water surface elevation η measured by the wave gauge mounted just beside the test cylinder as shown in Fig.1 is also demonstrated in these figure. The time variation of U demonstrated in Fig.8(c) shows that of incident wave, because the measuring point of U at $Y=-9\text{cm}$ is enough far from the test cylinder so that the existence of cylinder is negligible. We can recognize remarkably that the fluctuation of U at $Y=-2.3\text{cm}$ is large compared to that of U at $Y=2.3\text{cm}$. This is due to the fact that the major portion of vortex shedding and its activity take place on only one side of the cylinder, $Y<0$, as shown in Fig.7. In order to show the accuracy of the LDA measurement for the fluctuating velocity U , a comparison of velocity signals from the simultaneous measurement using the LDA and the hot wire anemometer which were placed at nearly same position at $X=0\text{cm}$ and $Y=-2.3\text{cm}$ is demonstrated in Fig.8(d). We can recognize that they almost agree except for very small velocity.

Figure 9 shows the relationship between the phase variations of pressures P at $\theta=90^\circ$ and $\theta=-90^\circ$, the

velocities U at $X=0\text{cm}$, $Y=-2.2\text{cm}$ and -2.2cm , the lift force F_y and free surface elevation η . The velocity U at $Y=2.2\text{cm}$ and the pressure P at $\theta=90^\circ$, and the velocity U at $Y=-2.2\text{cm}$ and the pressure P at $\theta=-90^\circ$ were measured simultaneously respectively. Although a little is known about boundary layer separation from the test cylinder in the present work, the points of $\theta=90^\circ$ and $\theta=-90^\circ$ seem to be near the separation point of it. The influences of the appearance of asymmetric vortex shedding on both phase variations of velocities U and pressures P are clearly recognized.

Fig.9 Phase variations of wave pressures P , velocities U and lift force F_y

Figure 10 shows the details of phase variation of the velocities U at the points of $X=0\text{cm}$, $Y=2.2\text{cm}$ and $Y=-2.2\text{cm}$, and the free surface elevation η . These records cover 5 cycles of the incident wave period and identify the origin of cycle. In order to investigate the influence of both the presence of the test cylinder and the vortex sheddings on the velocities U at these points, theoretical curves calculated from Stokes third order wave theory and linear diffraction wave theory are plotted in this figure. The measured velocities U at $Y=2.2\text{cm}$ is predicted quite well by

linear diffraction wave theory, but the velocity U at $Y=-2.2\text{cm}$ deviates markedly from the diffraction theory. We can

Fig.10 Details of phase variations of velocity U at $X=0\text{cm}$, $Y=-2.2\text{cm}$ and $Y=2.2\text{cm}$
 (—●— Linear diffraction wave theory)
 (- - - ○ - - - Stokes third order wave theory)

Fig.11 Distributions of wave velocities U around test cylinder at $X=0\text{cm}$ for $t/T=-0.1$ and $t/T=0.05$

recognize that the phase of U at $Y=-2.2\text{cm}$ proceeds faster than that of these wave theories. These may be due to the fact that the major portions of vortex shedding and its activity take place on the negative side of Y coordinate as described in Fig.7.

The distribution of measured horizontal velocity U at $X=0\text{cm}$ plotted at $t/T=-0.1(=0.9)$ and $t/T=0.05$ are shown in Fig.11 (a) and (b). In order to show the influence of the vortex shedding which appears mainly in the negative side of Y coordinate, see Fig.7, the theoretical curve of Linear diffraction wave theory is also plotted in these figures respectively. At $t/T=-0.1$, the crest of wave is approaching to the test cylinder and the peak value of F_y acts in the direction of negative Y coordinate as shown in Fig.7. In this case, the incident flow is passing from left to right with increasing the horizontal velocity U . The measured velocity U exceeds the value of Linear diffraction wave theory in the range of $-5\text{cm}<Y<-2\text{cm}$. This phenomenon, which is called the velocity enhancement by Grass et al.(1987), may be due to the existence of vortices which are shed and formed in the negative side of X coordinate during a last half wave cycle and then converted back over the negative side of Y coordinate. On the other hand, the measured velocity U near the test cylinder in the positive side of Y decreases as compared with the theoretical value. This phenomenon may be due to the existence of a counterclockwise circulation round the test cylinder. At $t/T=0.05$, the crest of wave has just passed through the cylinder and the incident flow is passing from left to right with decreasing the horizontal velocity. At this phase, the peak value of F_y appears in the direction of positive Y coordinate. The measured velocity U decreases in the range of $-3\text{cm}<Y<-2\text{cm}$ and increases just near the cylinder in the part of positive Y coordinate as compared with theoretical value. This phenomenon may be due to the existence of a clockwise circulation round the cylinder, which have been induced by the vortex sheddings from the surface of the test cylinder around $\theta=-90^\circ$.

In order to obtain a quantitative relationship between the flow around the cylinder and the lift force acting on it, following analysis was carried out. The lift force ΔF_{yc} acting on a vertical cylinder in waves may be estimated by Eq.(1), which is an approximation of Laggally's theorem and is equal to the Kuta and Jukovsky theorem as explained by Sawamoto et al.(1980).

$$\Delta F_{yc} = -\rho \Gamma U_0 \quad (1)$$

where ρ is fluid density, Γ is the total circulation around a cylinder induced by vortex sheddings, and U_0 is the incident horizontal velocity (=free stream velocity). If we suppose that the circulation Γ is evaluated by Eq.(2),

$$\Gamma = (U_1 - U_2) \cdot \pi \cdot D / 2 \quad (2)$$

the lift force ΔF_{yc} can be re-written as follow,

$$\Delta F_{yc} = -\rho \cdot (U_1 - U_2) \cdot \pi \cdot D \cdot U_0 / 2 \quad (3)$$

where U_1 and U_2 are the velocities at diametrically opposite surface points on the central cross-section of a cylinder.

Fig.12 Phase variations of lift forces
(● ΔF_{yc} , ○ ΔF_{ym})

Figure 12 shows the phase variation of ΔF_{yc} which was calculated by substituting the measured velocities u at $X=0\text{cm}$, $Y=-2.2\text{cm}$ and $Y=2.2\text{cm}$ into Eq.(3). The phase variation of the measurement lift force ΔF_{ym} , which is computed by integrating the measured surface pressure distribution around a test cylinder for several wave phases t/T , is also plotted in this figure. It is quite interesting that the calculation value of ΔF_{yc} evaluates quite well the phase variation of the measured lift force ΔF_{ym} in spite of very rough assumption is used in the calculation of ΔF_{yc} .

4. CONCLUSIONS

In this study, the unsteady characteristics of flow around a vertical cylinder in a wave have been obtained quantitatively by measuring the flow velocities U and the surface wave pressure P . The influence of the asymmetric vortex sheddings, which were obtained by a visualization of flow around the cylinder using video camera, to the velocities U and the surface wave pressures P have been obtained. The relationship between the flow velocities U near the boundary layer separation points on the cylinder surface and the lift force acting on a sectional part of it have been studied quantitatively by using a Kuta and Jukovsky theorem.

The dependence of a stable lift forces in waves on rms.KC number and wave depth parameter d/L is confirmed. However, farther depends of it on Reynolds number is not clear in the range of Reynolds number used in the present experiment.

CHAPTER 69

A Steady-State Wave Model for Coastal Applications

Dr. Donald T. Resio*

A steady-state spectral model is presented. This model produces a solution equivalent to a full time-stepping spectral model, but at much reduced computational times. Comparisons shown here demonstrate that the spectral model provides a good representation of shallow-water wave propagation phenomena and that wind effects can significantly influence near-coast wave conditions.

Introduction

Over the last twenty years a wide range of numerical models have been developed to assist coastal engineers, planners, and scientists in the estimation of near coastal wave conditions. Early models were based on monochromatic wave theory and ray tracing methods. Subsequently, models have developed along two lines, monochromatic and spectral. The major distinction between the two approaches pertains to the degree of randomness assumed in the physical system. If waves are primarily deterministic, variations in the phase function must be considered and nonlinear behavior of the type discussed by Yuen and Lake (1975) or Berkhoff (1976) can result. On the other hand, if waves are considered to be a random superposition of essentially linear components, nonlinear behavior must be treated as independent of phase. Nonlinearities of this kind relate to wave-wave interactions of the type discussed by Hasselmann (1962) and result in energy fluxes among the linear components which can become very important in shallow water (Resio, 1987, 1988). Also, as will be discussed later, diffusive energy fluxes due to spatial variations in energy can also be treated independent of consideration of the phase function.

In deep water, spectral models have gained a clear advantage in terms of being able to represent important aspects of wave generation, propagation and decay. In near coastal environments, some persist in using linear, monochromatic models (refraction diagrams, shoaling coefficients, monochromatic diagrams, etc.), however most

*President, Offshore & Coastal Technologies, Inc. (OCTI),
911 Clay Street, Vicksburg, MS 39180, U.S.A.

serious applications have now moved on to either spectral models or nonlinear models of combined refraction-diffraction of the type described by Berkhoff (1976) and Ebersole et al. (1986). Unfortunately, both of these classes of models require considerable computer resources for their execution. The purpose of this paper is to introduce a variation of spectral modeling which is much more efficient in terms of computer time and storage requirements than previous methods. The accuracy of this model and its potential application in various situations is then discussed.

Theoretical Considerations

Overview

Although all of the equations used below can be generalized to include the effects of currents, for simplicity and in order to express these equations in terms of energy densities rather than action densities, it is assumed here that currents are negligible. In this case in the absence of energy sources and sinks, we have

$$(1) \quad F(\underline{k}) = \text{constant}$$

along a wave range where \underline{k} is the wave number vector and $F(\underline{k})$ is the energy density at that point. Or, if energy sources and/or sinks are significant we have, along a ray \underline{s} ,

$$(2) \quad \frac{\partial F(\underline{k})}{\partial \underline{s}} = \sum S'_i(\underline{k}) \frac{\partial \underline{s}}{\partial t}$$

where S' represents a single source/sink term and t is time. In conventional spectral models, a spatial grid such as seen in Figure 1 is laid out. At each point in such a grid, an equation equivalent to (2) is solved

$$(3) \quad \frac{\partial E(f, \theta^x, y, t)}{\partial t} = \frac{\partial c c_g E(f, \theta^x, y, t)}{\partial x} c_{gx} + \\ \frac{2 c c_g E(f, \theta^x, y, t)}{\partial y} c_{gy} + \\ \sum S_i(f, \theta, x, y, t)$$

where $E(f, \theta^x, y, t)$ is the conventional spectral energy density in frequency-direction space, c is the phase velocity and c_g the group velocity, respectively, of waves with frequency f , x and y are orthogonal spatial axis, subscripts "x" and "y" denote component values in those directions, and $S_i(f, \theta)$ represents the effects of the i^{th} source term. The five-dimensional nature of (3) readily infers one of the major problems associated with its computer solution. The dependence of energy densities and sources on x, y, t have been explicitly written in equation (3) in order to point out this problem. In subsequent usage, dependencies on space and time will be assumed but not written; thus, $E(f, \theta, x, y, t)$ will now only be written as $E(f, \theta)$. At each point in the grid, equation (3) must be solved for each frequency-direction component over each

time stop. A "typical" number of frequencies and directions is about 300. If we use as an example a grid covering 10 miles by 10 miles with a spatial resolution of 1/4 mile, equation (3) must be solved about 80 million times in a simulation in order to achieve steady-state conditions (i.e., in order to perform the appropriate wave transformation).

Some groups have attempted to use a different approach to solve the problem of predicting near coastal wave spectra (Abernethy, et al., 1977). As seen in Figure 1, wave rays can be "backtracked" out from a point of interest. It is then possible to calculate equation (3) at each point along each of the rays shown there, provided that the form of the source terms in (3) are such that the spectral components can be considered as uncoupled. Unfortunately, the wind source term, wave-wave interactions and wave breaking are not treated adequately in this context. In all existing wave models, the net energy input into frequency components above the spectral peak becomes quite coupled by the normalization methods used to achieve a particular equilibrium range behavior. Also, the net source to the forward face due to wave-wave interactions and the redistribution of energy on the rear face depends on the local spectral shape. Similarly wave breaking depends on the total energy in the spectrum. Since information of this kind is not calculated, the source term treatment in such a model must necessarily be somewhat arbitrary and imprecise. Thus, if we seek an accurate solution to (3), we are left with the need to perform our calculations over an entire grid, rather than along rays passing irregularly through it. In this way all complete spectral information is available at each grid point and all source terms can be reasonably estimated.

Figure 1. Example of wave rays converging on Point A at the coast.

Let us assume that we are not interested in energy propagating away from a coast. Even if such waves exist they will not affect the incoming waves very much since the peak frequencies in incoming spectra will almost always be very different from the outgoing spectra. In this context,

all of the source terms and propagation effects can be seen to reside essentially within a half-plane. This is the key to recognizing a much more efficient solution method for steady state wave transformations.

The coastal wave transformation process can be regarded as one involving internal mechanisms (primarily wave-wave interactions and wave breaking) and external mechanism (primarily wind forcing and possibly some bottom interactions). For a given spectrum at the seaward boundary, if winds are relatively constant over the time span required for the waves to propagate across the grid (typically only 15 minutes to 1 hour for near-coast simulations), a simplified solution to (3) may be employed with essentially no loss of accuracy. In this context let us proceed to a solution of the transformations of the wave transformations from the first column to the second. An adequate solution for this problem can, by induction, be extended to the remainder of the grid.

Propagation

Since (3) is an inhomogeneous partial differential equation, solution techniques usually solve the homogeneous part first (essentially wave propagation) and then solves the inhomogeneous part (the effects of source terms). In order to avoid time consuming calculations, some simplifications are in order. If a ray passing from column 1 to column 2 does not pass through a caustic, Snell's law may be used to specify the angle and height variation from one depth to another

$$(4) \quad \theta_2 = \sin^{-1}(\theta_1 c_2 / c_1)$$

where subscripts "1" and "2" refer to the column locations. For waves which pass through a caustic, an approximate solution is used.

$$(5) \quad \theta_2 = 2 \tan^{-1}(\tan(\theta_1) \exp(-\frac{\partial c}{\partial h} \frac{\partial h}{\partial s} \Delta s / 2c_g))$$

where h is the local water depth and Δs is the distance along s from a point in column 1 to a point in column 2. Regardless of whether or not the wave ray passes through a caustic, it is assumed that $F(k)$ remains constant as it should for a conservative system. In terms of the frequency-direction form for spectral energy densities used in equation (3) this means that

$$(6) \quad cc_g E(f, \theta) = \text{constant}$$

which provides sufficient information for closure of the propagation problem. A modeling system based on this approach can be used to construct ray segments "piecewise" from column to column.

Divergence-Convergence Effects

Equation (6) is the typical form for wave propagation found in most spectral models today. Its validity as seen

here follows from the ray-based concept of wave propagation. However, if we examine the situation in Figure 2 as an example of a potential problem, we see waves propagating along the trough of a bathymetric feature. The wave ray traveling straight down the trough will not move to either side since the slope orthogonal to the ray path is zero. Whereas this may actually be true for the infinitesimal-width ray exactly in the center, it is not true for any rays displayed any distance whatsoever to either side. If, for example, all the energy in a spectrum were concentrated in that energy band propagating down the trough, the usual solution method would indicate that there would not be no change in wave height down the trough. It can be shown that, in general, the ray-based solution method does not represent divergence-convergence of wave rays over a grid cell. Thus, for a more accurate solution as may be warranted in sensitive applications, a divergence-convergence term is explicitly added to the solution method here. The form of this term is

$$(7) \quad \frac{\partial E(f, \theta)}{\partial t} = \nabla \cdot \Gamma_n$$

where Γ is the net flux of energy across a row boundary of the grid.

Figure 2. Example bathymetry for waves propagating over a crest.

Consideration of Diffraction in a Spectral Model

A detailed treatment of diffraction within the steady-state spectral model introduced here is considerably beyond the scope of this paper; however, a brief description of the general methodology will be given. First, one must recognize that since spectra are assumed to have random phases, phase relationships for a diffracted wave are only fixed between that wave and the individual component which created it. Thus, one cannot convert directly from a solution to the Fresnel Integrals and presume that the amplitude functions represent freely propagating waves. Instead, it is necessary to treat any phase-dependent

amplitude interaction in the context of a bound wave, bound to the spectral component which created it. However, it appears, as will be shown later, that phase-dependent solution techniques may only be required in situations with very steep energy cutoffs and very narrow spectral widths.

If we ignore phase effects, diffraction resembles a diffusion process. Any variation in wave amplitude along a wave creates results in a spatial redistribution and redirection of the wave energy. The following is used to represent the effects of diffraction in areas not affected by steep surface-piercing structures.

$$(8) \quad E_j(f, \theta_i)^{n+1} = \sum_{\kappa=-1}^{+1} \sum_{\lambda=-2}^{+2} \epsilon_{\kappa\lambda} E_{j+\kappa}(f, \theta_{i+\lambda})$$

where the subscript j refers to a grid row, i references an angle band, and $\epsilon_{\kappa\lambda}$ is a matrix of normalized multipliers.

Source/Sink Integration

The source terms employed in this model are similar to those discussed in Resio (1987, 1988). There are four source terms in the model:

1. wind inputs;
2. energy fluxes due to wave-wave interactions;
3. wave breaking; and
4. bottom interaction effects.

For all tests of source terms, bottom friction and other bottom interaction effects will be assumed to be negligible compared to nonlinear energy fluxes.

Tests of Steady-State Spectral Model

Tests of Propagation Only

A simple case to demonstrate that the spectral representation of refraction and shoaling used here is consistent with theoretical monochromatic results can be found in the propagation of waves with different periods and propagation directions across a slope with parallel depth contours. For this case, the monochromatic waves were approximated by a spectrum with energy in an angular band of one degree centered on the specified approach angle with a frequency band of 0.01 hertz. As seen in Table 1, the computed results show very good agreement with theoretical predictions.

Table 1
Wave Height Comparison

NOTE: a = theoretical result
b = model result

To test this model in a situation in which linear models are expected to be inaccurate, the model was run for the elliptical shoal, monochromatic test case described in Vincent and Briggs (1988), which is patterned after that of Berkhoff et al. (1982). The bathymetry for this case is shown in Figure 3. Figure 4 shows a comparison of the waves predicted by this model to those measured in the laboratory. Also shown in that figure are the modeled results of a finite difference solution to the "mild slope" equation (Ebersole et al., 1986). As seen there, the spectral model can reproduce the monochromatic, even for this nonlinear case, results quite well.

Figure 3. Laboratory set-up for waves over an elliptical shoal (from: Vincent and Briggs, 1988).

Figure 4. Comparisons of results from spectral model to laboratory measurements for monochromatic case.

Our next test drops the artificial constraint of monochromatic waves and examines model behavior for more realistic cases with reasonable wave spectra. Vincent and Briggs (1988) set up a series of laboratory tests on

bathymetry shown in Figure 3 in the directional wave basin located at the U.S. Army Engineer Coastal Engineering Research Center. The input spectrum tested here is shown in Figures 5 and 6. Waves were measured along a cross-section located about 17 feet behind the crest of the shoal as seen in Figure 3. Figure 7 gives a comparison of the steady-state spectral model's performance compared to the measured waves, along with the "equivalent" monochromatic solution (i.e. the solution obtained by treating these wave spectra as equivalent monochromatic waves). Clearly, the influence of spectral shape cannot be neglected. In fact, for waves typical of moderate storm conditions, the monochromatic approximation overpredicts wave heights by about 120%. Even for the case of a spectrum typical of swell, the monochromatic predictions are too high by about 100%. In neither of these test cases were waves observed to be undergoing wave breaking over the shoal; thus, the results shown in Figure 7 should be a fair examination of propagation effects only for realistic wave spectra.

Figure 5. Input frequency spectrum for test case.

Figure 6. Angular distribution of energy for test case.

Figure 7. Comparison of results from spectral model to laboratory measurements for broad directional spectrum. Equivalent monochromatic results shown for reference.

Tests of Propagation and Source Terms Together

As some final test cases, let us consider first a situation with a 40-knot wind blowing perpendicular to the coast over a planar shelf with constant slopes of 1/10 and 1/100. The boundary deep-water spectrum is specified to have a JONSWAP shape ($\delta = 3.3$, $f_m = 0.10$ hz, $\alpha = 0.013$, $\sigma_a = 0.07$, $\sigma_b = 0.09$) with a $\cos^{2\theta}$ angular distribution of energy. Table 2 shows the behavior of wave height as a function of distance from shore for the case with the wind source term included and for the case with the wind source neglected.

Next, let us consider a 40-knot wind blowing at an angle of 50° relative to the coast compared to the zero-wind case. Table 3 shows these results. Differences such as seen in Tables 2 and 3 could be very critical on sensitive projects.

Table 2

Comparison of Predicted Wave Heights (Metres) for 40-Knot Wind Blowing Straight Toward Coast and No Wind

Depth	Slope = 1/10		Slope = 1/100	
	No Wind	40-Knot Wind	No Wind	40-Knot Wind
90	6.11	6.11	5.84	5.97

20	0	1.5	0	14.9
10	0	0.9	0	6.3

Conclusions

A steady-state spectral model has been briefly described here. This model has a run time typically over 100 times faster than time-step solutions to comparable problems. Tests of this model support the following conclusions relative to shallow-water wave modeling:

1. The model described here, even neglecting phase-dependent behavior, can produce reasonable simulations of a wide range of wave conditions, both monochromatic and spectral, even in conditions which significant nonlinear behavior is expected;
2. Equivalent monochromatic methods cannot produce accurate results for realistic wave spectra; and
3. Simulations of areas on the scale of 5 miles or more should consider wind effects on nearshore waves; otherwise, the simulated results can deviate significantly from conditions expected under the action of winds.

CHAPTER 70

COMPARISONS OF NUMERICAL RANDOM WAVE SIMULATORS

by Josep R. Medina¹, M.ASCE, and
Carlos R. Sánchez-Carratalá²

ABSTRACT

A review of unidimensional numerical random sea simulators is provided, centering the attention on the measurement of distortions introduced by the different simulation techniques. Simulators by wave superposition are analyzed, with the conclusion being that they generate significant distortions on the realizations when the number of simulated points are larger than two times the number of wave components. Composed simulators are proposed for the purpose of generating long non-periodic realizations using FFT algorithms.

In order to qualify simulators, a justification, based on physical properties of random waves, is given to use m_0 , m_1 , Q_e and m_2 as the best spectral parameters to characterize processes. Mean values and variabilities of wave heights and periods are controlled by these parameters. A new robust technique is developed to estimate the parameters of an AR(p) model corresponding to a given target spectrum, $S_\eta(f)$. MA(q) and ARMA(p,q) approximations are studied. The source of pseudo-random numbers to generate the input white noise has a critical impact on the statistical properties of the output.

INTRODUCTION

Numerical random sea simulation techniques of stochastic processes defined by a continuous variance spectrum are used to solve numerous coastal and ocean problems. Numerical descriptions in time of the sea surface is a basic input of a variety of design methods in maritime engineering (Goda, 1985). On the other hand, given the increasing quality of the servo-control mechanisms for wave generation in laboratory, numerically synthesized records are also the input of most modern wave generators for physical modelling (see Funke and Mansard, 1987). Therefore, the numerical and physical experiments

¹Profesor Titular, Dept. Transportation, ETSI Caminos, Univ. Politécnicá de Valencia, SPAIN

²Research Asst., Dept. Transportation, ETSI Caminos, Univ. Politécnicá de Valencia, SPAIN

are the two main areas of application of numerical random wave simulators.

From the earlier papers of Borgman (1969) and Goda (1970), which showed engineering applications of linear simulators, a variety of random wave simulation approaches have been used in different numerical experiments. Hudspeth (1974) utilized a nonlinear simulator to predict wave forces on piles. Goda (1977) studied the statistical variability of ocean waves by analyzing the results given by a linear directional simulator. Hudspeth and Chen (1979) used linear and nonlinear unidirectional random wave simulators for the dynamic analysis of multilegged pile-supported ocean structures. Goda (1981) employed a linear directional simulator to study the directional resolution of different estimation techniques of directional spectrum. Goda (1983) and Elgar et al. (1984, 1985) used linear simulators to compare sea wave group characteristics of synthesized records with field measurements.

On the other hand, Funke and Mansard (1987) described a number of wave generation techniques in physical modelling, pointing out conceptual differences among wave generators and also the distance between numerical and physical simulations. However, most modern laboratory wave generators use numerically simulated waves as input of the servo-control element. Therefore, a first level of distortions is associated with the simulation technique itself and can be analyzed testing the corresponding numerical simulators.

Tuah and Hudspeth (1982) compared linear and nonlinear NSA and DSA FFT simulations; the result was that NSA synthesized records showed better statistical characteristics. Medina et al. (1985) gave a systematic contrast of linear simulators by wave superposition, pointing out the distortions induced by each simulator. Miles and Funke (1987) analyzed the limitations of the available numerical simulation techniques, which may be overshadowed in physical experiments, as a previous step to the installation of a multi-mode segmented wave generator at the NRC Hydraulics Laboratory.

This paper analyzes the different linear simulation techniques based on wave superposition, and also analyzes ARMA models to synthesize records by filtering white noise in the time domain. General criteria for qualifying simulators are given to rationalize the selection of a simulator for a given application. Finally, new AR simulators of low order and composed synthesizers are introduced with efficient methods to generate non-periodic realizations via FFT algorithms.

NUMERICAL SIMULATORS

Borgman (1969) pointed out the two main methods of generating realizations corresponding to an ergodic Gaussian process defined by its variance spectrum, $S_{\eta}(f)$.

The wave superposition method generates realizations by addition of sinusoidal functions with amplitudes and frequencies in accordance with $S_{\eta}(f)$ and random phases. The filtering of white noise produces realizations by passing a white noise through a linear filter, the transfer function of which is on a par with $S_{\eta}(f)$. The extension of the unidimensional simulation to 2D can be easily implemented by using wave superposition. However, said extension requires the design of new filters to propagate the simulations in the space by using white noise filtering (see Samii and Vandiver (1984)). Miles and Funke (1987) have studied the extension of the 2D simulation techniques to the 3D.

* Wave Superposition *

The linear simulators by wave superposition describe the vertical displacement of the sea surface by addition of sinusoidal waves:

$$\eta(n\Delta t) = z_n = \sum_{m=1}^M R_m \cos(2\pi f_m n\Delta t + \theta_m); \quad 0 < f_m < 1/(2\Delta t) \quad (1)$$

in which $\eta(n\Delta t)$ is a random time series of the ensemble corresponding to the stochastic process, discretized at time intervals Δt ; M is the number of wave components, R_m and f_m are the amplitudes and frequencies calculated from the wave spectrum of the process as

$$R_m^2/2 = S_{\eta}(f_m)\Delta f_m; \quad 0 < f_m < 1/(2\Delta t) \quad (2)$$

where Δf_m is the frequency interval related to the frequency component f_m ; and $S_{\eta}(f_m)$ is the variance spectrum characterizing the ergodic Gaussian stochastic process to be simulated. The real spectrum of the realization generated with Eq.1 is

$$S_{\eta}(f) = \sum_{m=1}^M (R_m^2/2)\delta(f-f_m); \quad 0 < f_m < 1/(2\Delta t) \quad (3)$$

in which $\delta(f)$ is the Dirac's Delta function.

Medina et al. (1985) analyzed a five step method for creating simulators by wave superposition; each step generates distortions on the results in the following manner: first, the target continuous variance spectrum, $S_{\eta}(f)$, needs a cut-off frequency lower than the folding frequency imposed by the aliasing phenomenon ($f_{max} < 1/(2\Delta t)$). Second, the linear assumption permits one to divide the target spectrum in M band spectra. Third, each band spectrum is substituted by a regular wave component with a frequency in the frequency band and an amplitude related (deterministically or non-deterministically) to the variance of the band spectrum. Fourth, a pseudo-random number generator will provide the random basis of the Monte Carlo experiment. Finally, efficient numerical algorithms can reduce the computational time which indirectly affects the quality of the simulator. According to Medina et al. (1985) simulations should be non-periodic, non-deterministic and should fit reasonably the spectral characteristics of the target spectrum. A general plan to qualify simulators,

given below, allows one to select the appropriate simulators from the large number of methods available.

* Filtering of White Noise *

The second general method to synthesize random realizations corresponding to an ergodic Gaussian stochastic process is the filtering of white noise through a linear filter. The general method is to define an ARMA filter, the transfer function of which corresponds to the target spectrum, $S_\eta(f)$. The autoregressive-moving average model (ARMA) is described by

$$\eta(n\Delta t) = z_n = -\sum_{k=1}^p a_k z_{n-k} + w_n + \sum_{m=1}^q b_m w_{n-m} \quad (4)$$

in which z_n is the time series generated, w_n is the white noise time series with variance σ_w^2 , a_k are the p autoregressive parameters, and b_m are the q moving-average parameters. The model described by Eq.4 is referred to as ARMA(p, q). From Box and Jenkins (1976), the spectrum of the realizations synthesized by the Eq.4 is

$$S_\eta(f) = 2\sigma_w^2 \Delta t |H(f)|^2 = 2\sigma_w^2 \Delta t \frac{|1 + \sum_{m=1}^q b_m \exp(-jm\Delta t 2\pi f)|^2}{|1 + \sum_{k=1}^p a_k \exp(-jk\Delta t 2\pi f)|^2}; \quad (5)$$

; $0 < f < 1/(2\Delta t)$

in which $H(f)$ is the frequency response function of the linear filter, Δt is the discretization time interval, σ_w^2 is the variance of the white noise input, and $S_\eta(f)$ is the target spectrum.

Taking into consideration that simulators by wave superposition tend to generate periodic or deterministic realizations of long duration, the filtering of white noise avoids these problems. Unfortunately, the calculation of the ARMA parameters to fit the target spectrum and the source of white noise are elements which can also produce large distortions on the results.

CRITERIA TO QUALIFY SIMULATORS

The selection of a numerical simulator (or the corresponding physical generator) to carry out a numerical (or physical) experiment depends on the available criteria to qualify the simulators. To establish a general plan for qualifying simulation techniques is essential for selecting appropriate simulators for specific problems.

A realization of a process defined by a continuous variance spectrum can not be periodic. As a result, harmonic simulators should be avoided, including those long simulations based on FFT algorithms. On the other hand, according to Medina et al. (1985), a sinusoidal function can be considered a deterministic autoregressive process AR(2) with two parameters and, therefore, the time series given by Eq.1 only have $2M$ non-deterministic points. Consequently, the length of simulations by wave superposition should be limited to $2M$ points. Finally, the simulated process should have spectral characteristics which are similar to the target process. A number of opinions and parameters have been given and it is not

clear what the best parameters are for characterizing target spectra.

* Suitable Spectral Characteristics *

What are the most appropriate spectral parameters to characterize variance spectra?. This question has not as yet been answered and the solution probably depends on the engineering application in which the spectral description is used. However, some properties of random signals can be taken into consideration to give a reasonable answer.

If $\eta(t)$ is the sea surface elevation with the spectrum $S_{\eta}(f)$, the spectral moments are defined as

$$m_n = \int_{f_{\min}}^{f_{\max}} f^n S_{\eta}(f) df \tag{6}$$

and therefore, the variance of the vertical displacement of the sea surface, $\eta(t)$, is $\sigma_{\eta}^2 = m_0$; the variance of the vertical velocity, $\dot{\eta}(t) = d\eta(t)/dt$, is $\sigma_{\dot{\eta}}^2 = (2\pi)^2 m_2$; the variance of the vertical acceleration, $\ddot{\eta}(t) = d^2\eta(t)/dt^2$, is $\sigma_{\ddot{\eta}}^2 = (2\pi)^4 m_4$; the mean period of the orbital movement of sea surface is $T_{03} = m_0/m_1$; the mean zero-up-crossing period is $T_{02} = (m_0/m_2)^{0.5}$; and the mean crest-to-trough period is $T_{24} = (m_2/m_4)^{0.5}$. Other mean periods can be defined although no easy physical interpretation can be given.

According to Blackman and Tukey (1959) the variability of the variance of the process depends on the spectral peakedness. Using the dimensionless spectral peakedness parameter Q_e , given by Medina and Hudspeth (1987)

$$\frac{\sigma(z_{rms})}{E(z_{rms})} = \left(\frac{Q_e/8}{N\Delta t/T_{01}} \right)^{1/2} \tag{7}$$

in which

$$Q_e = (2m_1/m_0^3) \int_{f_{\min}}^{f_{\max}} S_{\eta}^3(f) df \tag{8}$$

Therefore, the spectral moments are not the only parameters necessary for defining the stochastic properties of the simulations. As noted by Medina and Hudspeth (1987), the dimensionless spectral peakedness parameter Q_e is not only related to the variability of the variance, but also to the wave grouping characteristics. A general order of parameters can be suggested for the most common applications:

- 1.- The most important parameter is the total variance of the process, $\sigma_{\eta}^2 = m_0$. This parameter controls the magnitude of wave heights, which have a major impact on most engineering applications.
- 2.- Fixed $\sigma_{\eta}^2 = m_0$, the first moment, m_1 , determines the mean period of the orbital movement of the sea surface, $T_{01} = m_0/m_1$. The mean wave periods are probably the second most important variable for maritime engineering applications.
- 3.- Having characterized the mean values of wave heights and periods by m_0 and m_1 , the third most important parameter should control the variability of variance.

The dimensionless spectral peakedness parameter Q_e , shown in Eq.8, can characterize the variability of variance. This variability is also related to wave groupiness, variability of significant wave height, and other basic sea state parameters.

- 4.- The fourth most important parameter can be the second spectral moment, m_2 , because the variability of periods tends to be dependent on the parameter $\nu = (m_0 m_2 / m_1^2 - 1)^{1/2}$ given by Longuet-Higgins (1975). Hudspeth and Medina (1988) give stochastic properties of the instantaneous frequency as function of ν .

SIMULATION BY WAVE SUPERPOSITION

Using the criterion of non-periodic realizations, the Goda's (1970) and Borgman's (1969) simulators could be considered more suitable than the harmonic DSA and NSA simulators given by Tuah and Hudspeth (1982). However, the criterion of non-deterministic realizations would only permit one to use those non-harmonic simulators for short realizations (2M points), while DSA and NSA simulators can generate large non-deterministic realizations with the same computational time. The non-periodic realizations obtained from non-harmonic simulators by wave superposition progressively distort the stochastic properties when the number of simulated points increase by more than 2M.

The periodicity of DSA and NSA FFT simulations can be avoided by modulating the simulations by a basic frequency, f_0 , non-harmonic of $\Delta f = 1/(N\Delta t)$. However, the envelopes of these simulators are periodic $N\Delta t$, a fact which is also an undesirable characteristic. By composing non-harmonic FFT simulators it is possible to get non-periodic realizations with non-periodic envelopes of an indefinite length.

Goda (1977, 1981), and Miles and Funke (1987) present different aspects of the extension of simulators by wave superposition to 3D. As noted by Goda (1977) and Medina et al. (1985), the addition of many waves with the same frequency and random phases in directional simulation generates random unidimensional realizations given by Eq.1, but the amplitudes are non-deterministic, and can be modelled by

$$R_m^2/2 = (C_m/2) S_{\eta}(f_m) \Delta f_m = -\ln(U_m) S_{\eta}(f_m) \Delta f_m; \quad (9)$$

$$; m=1, 2, \dots, M$$

instead of the deterministic relation given by Eq.2. U_m and C_m are random variables uniformly and chi-squared distributed with two degrees of freedom. The Eqs.2 and 9 correspond to the relation between DSA and NSA simulators described by Tuah and Hudspeth (1982). The simulators, based on Eq.9 instead of Eq.2, are also named "random Fourier coefficient" (RFC) methods to differentiate them from the "random phase" methods (RP) used by Miles and Funke (1987). DSA (RP) simulators via FFT can be modified to generate non-harmonic simulations. Considering ocean spectra are zero for low frequencies, one can select a

basis frequency , f_0 , non-harmonic of $\Delta f=1/(N\Delta t)$ and then

$$\begin{aligned} \eta(n\Delta t) &= z_n = \sum_{m=1}^M R_m \cos(2\pi(f_0+f_m)n\Delta t + \theta_m) = \\ &= \sum_{m=1}^M R_m (\cos(2\pi f_0)z'_n - \sin(2\pi f_0)\hat{z}'_n) \end{aligned} \quad (10)$$

in which

$$z'_n = \sum_{m=1}^M R_m \cos(2\pi f_m n\Delta t + \theta_m) \quad (11)$$

and \hat{z}'_n is the Hilbert transform of z'_n . The time series simulated by Eq.10, z_n , have longer periods than $N\Delta t$. For instance, if $f_0=(5+1/7)\Delta f$, the period of the realizations given by Eq.10 is $7N\Delta t$; however, the realizations would have envelopes with a period of $N\Delta t$. The composition of simulators enlarges the period of time series and envelopes. By taking several non-harmonic frequencies f_0 and composing simulators, it is possible to generate, via FFT, almost non-periodic realizations with non-periodic envelopes.

The simulators by wave superposition fit the spectral characteristics well. Periodicity and deterministic behaviour can be studied by analyzing the variability of the variance of long simulations. Fig.1 shows the representation of the C.V. of z_{rms} calculated from forty realizations using DSA and NSA simulators and the method

Fig.1: Coefficient of Variation of z_{rms} in long simulations. The graph shows the mean values from 40 DSA and NSA simulations of JONSWAP ($N=1024$, $\Delta t=0.5$ s, $\gamma=1$, $f_0=0.0635$ Hz, $f_{max}=1/(2\Delta t)$), compared with results of Borgman's simulator with different number of wave components and composed non-harmonic FFT simulator with 4 components. "I" is the number of points of the simulation.

proposed by Borgman (1969) with different number of components. DSA simulations have unrealistic low variabilities when N approximates to $1/(\Delta f \Delta t)$ while NSA simulators have variabilities as predicted by linear theory, up to the full period of simulation. Borgman's simulator only gives reasonable variabilities if the number of components is large in comparison with the number of points in the simulations analyzed ($M > N/2$).

FILTERING WHITE NOISE

The filtering of white noise generated by Eq.4 can theoretically produce indefinitely non-periodic and non-deterministic realizations with a prescribed variance function, by only taking the appropriate ARMA parameters to fit the target spectrum according to Eq.5. However, these simulators have two critical points: the source of white noise and the method to determine the ARMA parameters.

The spectrum of the output of the linear filter given by Eq.4 is the square of the absolute value of the frequency response function, $|H(f)|^2$, multiplied by the spectrum of the input (white noise). Unfortunately, the spectrum of random time series generated by computer can depart from the perfect white shape, even though the time series passes the usual tests of randomness. Hull and Dobell (1962) pointed out the extreme difficulty in justifying the random behaviour of numerically synthesized white noise time series. Additionally, these simulators require a precise and robust enough methodology to determine the ARMA parameters to fit the target spectrum.

AR(p)

If only the autoregressive parameters in Eq.4 are considered, the process is then described by

$$\eta(n\Delta t) = z_n = - \sum_{k=1}^p a_k z_{n-k} + w_n \quad (12)$$

and the spectrum of the output is related to the set of parameters by

$$S_\eta(f) = \frac{2\sigma_w^2 \Delta t}{\left| 1 + \sum_{k=1}^p a_k \exp(-jk\Delta t 2\pi f) \right|^2}; \quad 0 < f < 1/(2\Delta t) \quad (13)$$

in which a_k are the p autoregressive parameters. Holm and Hovem (1979) presented a method for describing sea states by an AR filter with 15 to 30 parameters, while Houmb and Overvik (1981) proposed the inclusion of a fixed MA parameter to a basic AR(34) model.

Spanos and Hansen (1981), Spanos (1983), and Spanos and Mignolet (1986) have analyzed different methods to calculate the AR parameters corresponding to a known spectrum. The equations of Yule-Walker can be derived from Eq.12 which leads to the corresponding Toeplitz matrix equation system. For JONSWAP or PM spectra, the solution of this system gives a spectrum with correct spectral

moments but sharp fluctuations about the mean value (good m_0 , m_1 and m_2 but bad Q_e). Increasing the number of parameters, p , the Toeplitz matrix becomes gradually ill conditioned and the solution is unstable. As noted by Spanos and Mignolet (1986) a stable finite AR representation exists and admits an inverse MA representation if and only if

$$\int_0^{f_d} \log(S_\eta(f))df > -\infty; f_d = 1/(2\Delta t) \tag{14}$$

where f_d is the folding frequency. This relation is not satisfied by the PM spectrum and although Spanos (1983) proposed a sophisticated method to improve the solution by approximated spectral shapes, Spanos and Mignolet (1986) concluded that it "is not permissible to determine a

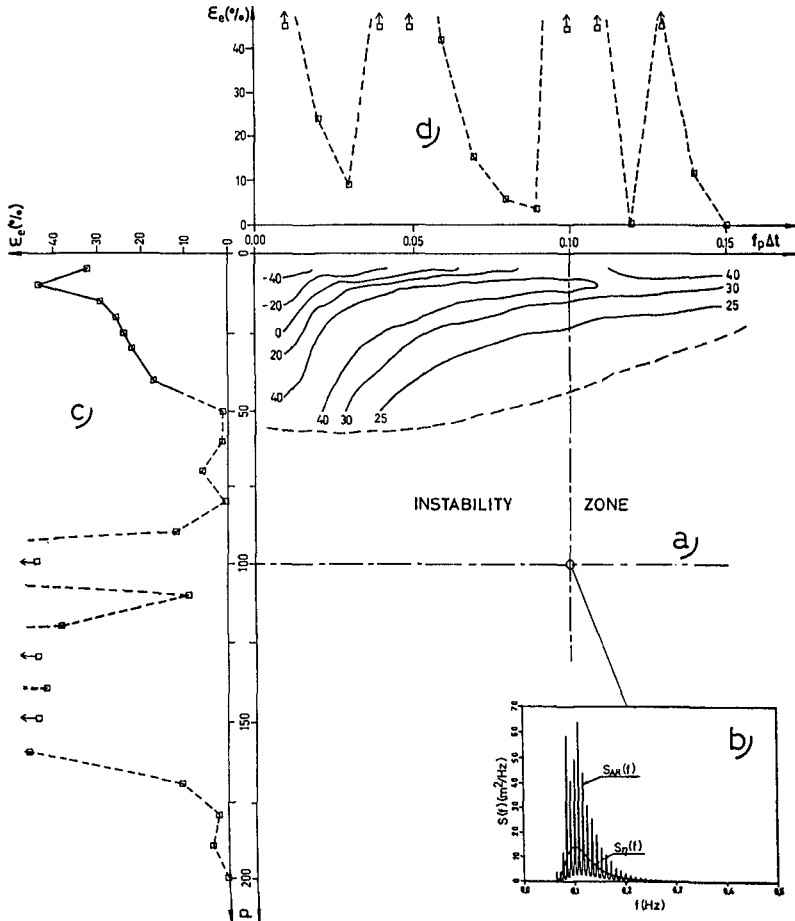

Fig.2: Classic AR approximation: a) Map of errors E_e ; b) Typical target and AR spectra; c) Values of E_e with $\Delta t f_p = 0.1$; and d) Values of E_e with $p = 100$. The target spectrum is JONSWAP ($N = 1024$, $\gamma = 1$, $f_p = 0.1$ Hz, $f_{max} = 1/(2\Delta t)$)

reliable AR representation of the PM spectrum in a straight forward manner"; and they consequently proposed ARMA models for simulations of ocean spectra.

From Eq.14 it is easy to infer that the instability of the AR model is generated by the frequencies with low energy. A simple method for eliminating the zeros in $S_\eta(f)$ is to add a very low level of white noise to the process which is to be simulated. The addition of a white noise with a variance of 0.1% to 0.3% of the total variance can solve the instability problem and generate an admissible level of distortions in simulations because larger noise intensities are always present in Nature and Laboratories for most common ocean engineering applications. The consideration of a very low level of white noise on the target spectrum (whose variance is detracted first from the spectrum) before the calculations of AR parameters using Yule-Walker equations will be referred to as the proposed new robust method.

Fig.2-a shows the map of relative errors of the peakedness parameter Q_e , which is sensitive to fluctuations around the target spectrum. The map of relative errors of Q_e , ξ_e , shows a region of instability in which small differences in parameters or variables of simulation can critically change the simulator. The relative error ξ_e is defined as

$$\xi_e = (\hat{Q}_e - Q_e) / Q_e \quad (15)$$

in which \hat{Q}_e is the spectral peakedness parameter corresponding to the fitted AR approximation. Although the errors of the target spectral moments are low, these simulators show very large errors of Q_e . Fig.2-b shows a typical AR spectrum, as compared to the target spectrum.

On the other hand, Fig.3-a shows the map of errors of ξ_e for the proposed new robust method, adding a white noise of variance 0.25% m_0 to the target spectrum. The new AR approximations are stable and much better for higher order p . The new errors of spectral moments m_1 and m_2 are less than 1%, if $f_p \Delta t > 0.1$, and show a monotonic decreasing behaviour with p and $f_p \Delta t$. Therefore, the proposed new method to determine AR approximations can be considered superior to the classic method, and it is applicable to a variety of ocean spectra.

MA(q)

Taking only the moving average parameters in Eq.4, the MA(q) model is described by

$$\eta(n\Delta t) = z_n = w_n + \sum_{m=1}^q b_m w_{n-m} \quad (16)$$

The spectrum of the output is then

$$S_\eta(f) = 2\sigma_w^2 \Delta t \left| 1 + \sum_{m=1}^q b_m \exp(-jm\Delta t 2\pi f) \right|^2; \quad 0 < f < (1/2\Delta t) \quad (17)$$

in which b_m are the q moving average parameters. Kimura and Kimura (1987) have presented a method to

Fig.3: New robust AR approximation with 0.25% of white noise: a) Map of errors E_e ; b) Typical target and AR spectra; c) Values of E_e with $\Delta t f_p = 0.1$; and d) Values of E_e with $p = 100$. The target spectrum is JONSWAP ($N = 1024$, $\gamma = 1$, $f_p = 0.1$ Hz, $f_{max} = 1/(2\Delta t)$)

determine the parameters of a $MA(q)$ approximation for a given target spectrum, $S_\eta(f)$. The method basically consists of the calculating of the parameters of an $AR(q)$ approximation to $S_\eta(f)$ and then the calculating of the $MA(q)$ parameters by

$$\sum_{m=0}^i a_{i-m} b_m = \delta_i; \quad i = 0, 1, \dots, q \tag{18}$$

in which δ_i is the discrete Dirac's Delta function, and $a_0 = b_0 = 1$ using Eq.16 for the $MA(q)$ model. The proposed method by Kimura and Kimura (1987) is equivalent to the solving of the equations of Yule-Walker and to the determining of the MA parameters, using Eq.18. The parameters of the $AR(q)$ model corresponding to $S_\eta(f)$ are

the same as the parameters of the MA(q) model fitted to $1/S_\eta(f)$, which is the inverse filter of the MA(q) model fitted to $S_\eta(f)$. Eq.18 reflects the relations between the parameters of these two inverse MA filters.

Obviously, the quality of the MA(q) approximation proposed by Kimura and Kimura (1987) depends on the AR(q) model taken as basis. The proposed new method to estimate robust AR parameters given in the previous section is also useful for getting better MA(q) approximations. Fig.4 shows a typical evolution of errors generated by the MA(q) model based on a robust AR(q) estimation with 0.25% of white noise. The relative error of Q_e , ϵ_e , is compared with the corresponding relative errors of m_1 , ϵ_1 , and m_2 , ϵ_2 , as well as with the relative error of Q_e for the AR(q) model taken as basis.

Fig.4: Errors ϵ_e , ϵ_1 , ϵ_2 of MA approximation based on the new robust AR model with 0.25% of white noise. The values are compared with the ϵ_e of the AR model. The target spectrum is JONSWAP ($N=1024$, $\Delta t=1.0$ s, $\gamma=1$, $f_p=0.1$ Hz, $f_{max}=1/(2\Delta t)$)

ARMA(p, q)

Spanos and Mignolet (1986) have proposed two alternative procedures to obtain the unknown coefficients a_k and b_m in Eq.5 to fit the target spectrum, $S_\eta(f)$. The methods are based on the work of Samarasinghe et al. (1985) and Graupe et al. (1975).

*** Auto/Cross-Correlation Matching (ACM) ***

This method is based on a first representation of the process by an AR filter, followed by the equalization of the autocovariance of the output and the cross-covariance of input-output.

* Power Order Matching (POM) *

This technique is based on the equalizing of the z powers of the transfer functions of the ARMA and AR model, which is used as the basis. It can be shown that this method is equivalent to matching the cross-covariance of input-output of the AR and ARMA approximations for $i=0$ to $p+q$.

* Evaluation of ACM-POM *

The quality of these simulators depends on the AR approximation used as basis. Spanos and Mignolet (1986) show good ARMA approximations ACM(7,7) and POM (8,8); but those results were based on special satisfactory AR(100) model which used a Taylor expansion approximation of the PM spectrum. The models proposed by Spanos and Mignolet (1986) are only valid for a specific spectrum and for simulation characteristics (Δt , p , and q). Changes in Δt , p , and q can produce unsatisfactory results.

Using the proposed new robust technique to estimate the AR(m) approximation, the ACM and POM methods have been applied to a JONSWAP spectrum ($\gamma=1$, $f_p=0.1$ Hz, $f_p \Delta t=0.1$). The results for $p=q$ show local good approximations that can not be generalized for different target spectra. Larger orders of filtering do not generate better filters.

CONCLUSIONS

After analyzing and contrasting different unidimensional numerical random sea simulations, the following conclusions can be stated:

- 1.- The stochastic properties of simulations by wave superposition are distorted when the number of points of the simulations are larger than two times the number of wave components.
- 2.- Composing modulated DSA simulators, efficient non-harmonic realizations via FFT can be generated.
- 3.- The spectral parameters m_0 , m_1 , Q_e , and m_2 have been analyzed, justifying this rational sequencing of parameters to characterize the appropriate spectral shapes. They are related to mean value and variability of wave heights and periods.
- 4.- A new robust method for determining the AR(p) model for a given target spectrum is given. The method is based on the addition of a very low level of white noise to the target spectrum and then the solving of the Yule-Walker equations.
- 5.- The MA(q) and ARMA(p,q) approximations to the basic AR(m) model have been analyzed. The MA(q) are competitive.
- 6.- Simulators by filtering white noise are quite sensitive to the spectral characteristics of the method used for generating the white noise time series.

CHAPTER 71

STORM STATISTICS IN THE NORTH SEA

By

B.A. Salih¹, R. Burrows² and R.G. Tickell³

1.0 INTRODUCTION

Effective planning of offshore activities requires statistical information detailing storm occurrences and durations (defined as exceedences of an H_s threshold). This information is often referred to as persistence.

The frequency of storm events and the probability associated with a number of successive sea states being above (or below) a given threshold level is often required by engineers to estimate the potential work period and down-time as well as to incorporate the lead and lag times needed to stop and restart interrupted operations due to severe weather conditions.

However, until recently, a lack of sufficiently long data bases has precluded any meaningful investigation of this nature. Unrepresentative or misleading results can follow from data records that were measured over only a limited number of years. Furthermore, significant distortions may be introduced if the data record is not continuous as data gaps interrupt the persistence pattern.

As more recorded data have become available, concerted efforts have been made on this topic; most notably by Houmb and Vik who developed a probabilistic model describing the statistics of storm (and calm) durations and frequencies at varying levels of sea state intensity.

The present study investigates the adequacy of the semi-empirical procedure proposed by Houmb and Vik and also discusses the development of two new modelling techniques. The performance of these models are examined against wave data measured at the BP Forties field in the North Sea. A number of new statistical descriptors relating to the profile and intensity of storms have also been developed.

It is recognised that wave period (T_z) and directional information must ultimately be incorporated in a storm climate model. However, this is beyond the scope of the present discussion.

1.1 DEFINITIONS

In the work reported here, the definition of storm events as proposed by Houmb & Vik (1976) is adopted:

A storm is defined as a period of time during which the significant wave height, H_s , exceeds a threshold α (see Figure 1). The onset of a storm condition at α is marked by an upcrossing of the level $H_s = \alpha$. Measures of storm (D_s), calm (D_c) and storm inter-arrival (D) durations are also indicated.

Figure 1: Definition of storm occurrences and durations.

1.2 DATA

The data used in this study have been measured at the BP Forties Field located in the North Sea.

The original data bank contained measurements extending over the period from June 1974 to December 1981. Measurements of significant wave height based on 20 minute recordings of sea surface elevation were made using Wave Staff and Wave Rider Buoy instruments. Unfortunately, the data is not continuous. In some cases measurements are missing over periods of up to several months. Owing to the importance of a continuous data set for the assessment of storm statistics, the data was subjected to a rigorous treatment and various steps were followed to compensate for data gaps (see Salih, 1987). As a result, it was possible to extract 5 years of almost continuous data covering the period from January 1977 to December 1981.

1.3 RESULTS AND DISCUSSION

1.3.1 Houmb and Vik Model

Initially attention is focused on the semi-empirical procedure proposed by Houmb and Vik (1977) and later developed by Pastene-Beytia (1976) and Dale (1979). The analysis of threshold crossings yields that the storm frequency at a given threshold is expressed as:

$$f_s(\alpha) = \frac{C(\alpha - A)^{C-1}}{B^C \sqrt{2\pi}} \sigma_{\dot{H}_s|\alpha} \exp\left[-\left(\frac{\alpha - A}{B}\right)^C\right] \dots\dots\dots(1.1)$$

Where $\sigma_{\dot{H}_s|\alpha}$ is the standard deviation of the first time derivative of the H_s time trace at the sea state level α , and A, B and C are the pa-

rameters of the Weibull distribution approximating $p(H_s)$.

The expression is derived utilising the main assumptions that:

a) The marginal distribution of H_s can be approximated by a 3-parameter Weibull pdf. The validity of this has been demonstrated by many studies in the field of Long-Term wave statistics (see Burrows et al, 1986). The analysis of the Forties data supports the Weibull distribution as an accurate description the probability 'mass' and the extreme tail of the H_s distribution.

Nevertheless, the Weibull distribution is often noted for its poor representation of the lower values of H_s . Thus the use of alternative distributions such as the Log-Normal, as proposed by Ochi (1978), and the NMI modified Log-Normal, proposed by the National Maritime Institute (and now British Maritime Technology) (see Fang et al, 1982) has also been assessed against observations. Statistical goodness-of-fit tests, however, has established the Weibull distribution as a superior descriptor of the observed $p(H_s)$ (see Salih, 1987).

b) The second important assumption in the procedure is that the distribution of $\hat{H}_s|H_s$ can be represented by a mean-zero Gaussian distribution with a variance, $\sigma^2_{\hat{H}_s|H_s}$ that linearly varies with level α .

Figure 3:
Variation of standard
deviation of $H_s|H_s$
with H_s thresholds.

Figure 2 and Figure 3 point to the acceptability of both these assumptions. Houmb & Vik noted no seasonal variation in the $\sigma_{Hs|\alpha}$ versus α relationship. An alternative procedure for storm modelling proposed by Graham (1983) implies that there is no seasonal variation in the relationship between $\sigma_{Hs|Q(Hs)}$ and $Q(Hs)=1-P(Hs)$.

The results of this study, however, indicate the existence of a systematic seasonal variation in the relationship in question. It can be noted from Figure 3 that the summer and winter months' linear relationships fall on either sides of the average 'yearly' $\sigma_{Hs|\alpha}$ versus α relationship.

This systematic variation has been taken as a justification to parameterise the linear relationship (in the form of $\sigma_{Hs|\alpha} = \kappa \alpha$) in terms of Hs statistics. As the main input to the storm model are the Weibull fit parameters, the slope of the straight line, κ , has been regressed against A, B and C and the following least square relationship has been found to provide reasonably accurate estimates:

$$\kappa = 0.0476 A^{0.201} B^{0.116} C^{0.185} \dots\dots\dots(1.2)$$

The expression of Equation 1.2 has been used to predict frequencies of storm events at varying levels of sea states and have been found to compare favourably with observations as can be seen from Figure 4. The different curves arise from the use of the Weibull and NMI modified Log-Normal distributions for $p(Hs)$ and the average 'yearly' estimates of $\sigma_{Hs|Hs}$.

Figure 4: Average frequency of storm occurrences with prediction from Houmb & Vik model.

The average duration of storms, $\bar{D}_S(\alpha)$, can be obtained from Equation 1.1 as

$$\bar{D}_S(\alpha) = \frac{\text{Total time } (Hs > \alpha)}{\text{Total number of storms}} = \frac{1-P(Hs)}{f_S(\alpha)}$$

$$\bar{D}_S(\alpha) = \frac{B^C \sqrt{2\pi}}{C(\alpha - A)^{C-1} \sigma_{Hs|\alpha}} \dots\dots\dots(1.3)$$

The average durations of calms, defined as non-exceedence of the α level, and the average inter-arrival of storms (and calms) can be expressed as:

$$\bar{D}_c(\alpha) = \frac{F(\alpha)}{f_c(\alpha)} = \frac{1.0}{f_c(\alpha)} - \bar{D}_s(\alpha) \dots\dots\dots(1.4)$$

Hence the average duration of storm inter-arrivals at level α becomes:

$$\bar{D}_i(\alpha) = \bar{D}_s(\alpha) + \bar{D}_c(\alpha) = \frac{1.0}{f(\alpha)} \dots\dots\dots(1.5)$$

Average durations evaluated from Equation 1.3 to Equation 1.5 are compared with observations in Figure 5; again the modelling procedure closely approximates the observed behaviour. The noted discrepancy between long durations, in part at least, arises from sampling problems and also in how to deal with long sequences which extend beyond the seasonal date windows (ie storms in February, say, terminating in March or starting in January).

Figure 5: Average Durations of storms, calms and storm inter-arrivals with predictions from Houmb & Vik model.

1.3.1.1 Distribution of Durations

The use of a basic Poisson model for the description of storm events has been argued by Houmb & Vik. The suitability of this model requires that: (a) the arrival rate of storms is stationary, (b) the probability of storm occurrences in a short interval of time is proportional to the length of the interval and (c) the probability of multiple storm events in a short period of time is insignificant compared to a single event.

If the storm events are described by a Poisson model, then distribution of storm durations is exponential. Whilst some of the theoretical

justification for the adoption of exponential model for storm durations follows from a Poisson assumption for storm events, as indicated by Houmb and Vik, the underlying assumptions are not fully satisfied in practice. Houmb & Vik, however, found little empirical evidence to support this and instead proposed the use of the more general 2-parameter Weibull distribution. Dale (1979) reports, nevertheless, that the distribution of storm durations at Seven Stones' light vessel off the South West coast of England become exponentially distributed at higher threshold levels of sea state.

Figure 6 points to the general acceptability of the Weibull model and also confirms Dale's observation that the distributions, towards the higher thresholds, become exponential. This is perhaps an indication that the assumptions inherent in the Poisson model become more valid at these thresholds.

Figure 6: Distribution of storm durations with 2 parameter Weibull model superimposed.

1.3.2 Gaussian Transformation Model

It was anticipated that the technique of transforming a general set of correlated random variables into the Gaussian form would enable the utilisation of the wealth of theory available for Gaussian processes.

The time series of $H_s, H_s(t)$, modelled by a Weibull distribution can be transformed into a mean-zero Gaussian process, $X(t)$, of unit variance by applying the approximate formulae for Gaussian transformation given by Abramowitz & Stegun (1964),

$$X(t) = f - \frac{C_0 + C_1 f + C_2 f^2}{1 + d_1 f + d_2 f^2 + d_3 f^3} + \text{error} \dots\dots\dots(1.6)$$

where $|\text{error}| < 0.00045$, and

$$f = \sqrt{\ln\left(\frac{1}{Q(H_s(t))}\right)} \dots\dots\dots(1.7)$$

$Q(H_s(t))$ is the exceedence probability of $H_s(t)$ ($\int_{H_s(t)}^{\infty} p(H_s) dH_s$).

The basis of this procedure is illustrated diagrammatically in Figure 7. The original process, $H_s(t)$, and its Gaussian transform peak jointly

and crossings of the level $H_s = \alpha$ corresponds to crossings of $X = \beta$ in the transformed domain.

Figure 7: Gaussian transformation of random variables using distribution functions.

The Gaussian transform of $H_s(t)$ is characterised by a wide band power spectrum. Estimates of the spectral band width parameter, ϵ , derived from duration statistics, are found to be approximately 0.950 for summer months and 0.965 for winter months.

Various storm characteristics can be expressed in terms of the standard deviation of X , which is unity by virtue of Equation 1.6, and that of the first time derivative of X , \dot{X} , using results of the classical mathematics associated with stationary Gaussian processes. The frequency of storm occurrences is equivalent to the frequency of up-crossings of the level β ,

$$N^+(\beta) = \frac{1}{2\pi} \frac{\sigma_{\dot{X}}}{\sigma_X} \exp\left[-0.5 \left(\frac{\beta}{\sigma_X}\right)^2\right] \dots\dots\dots(1.8)$$

The frequency of up-crossing by $H_s(t)$ of the sea state threshold level of α can be obtained as

$$N^+(\beta) = N^+(\alpha) \dots\dots\dots(1.9)$$

The average durations can be deduced by the same arguments followed to obtain Equation 1.3 through Equation 1.5

In order to justify the application of the theory of stationary Gaussian processes, the problem of non-stationarity has been avoided herein by considering monthly periods. This implies that the statistics for monthly periods are assumed stationary from year to year.

The predictions of average storm, calms and inter-arrival duration arising from the use of this technique are found to compare favourably with the observed behaviour as can be noted from Figure 8. The predictions are also presented in Table 1 alongside estimates obtained from the Houmb and Vik procedure. It is apparent the transformation technique provides, on the whole, the more accurate predictions.

Table 1. Average duration of storms and inter-arrivals with predictions from Houmb & Vik, Gaussian Transformation and Markov models

The main advantage of the transformation technique is that additional statistical descriptors of 'storm shape' can be established from theory. In particular, the distribution of peak amplitudes of a wide-banded Gaussian process can be used to predict the distribution of peak H_s attained within the duration of a storm. This aspect is to be discussed in a later section.

Furthermore, the technique enables more complex measures of storm statistics to be developed; the theory relating to Gaussian processes can be utilised to establish probability distribution of storm duration. Price and Bishop (1974) derive a distribution for exceedence duration by following a method originally proposed by Rice (1944,1945) However, the resulting expression is inherently complex and requires the evaluation of various higher order spectral moments. In the absence of a long stationary data base, such spectral moments cannot be reliably determined and in subsequence this aspect has not been pursued in the present study.

1.3.3 Markov Chain Model

The use of the first order Markov chain theory to model the time series of Hs requires that only successive sea states, Hs_i and Hs_{i+1}, are statistically correlated. In reality, however, sea states several time steps apart may exhibit appreciable statistical correlation. Thus, at first the validity of the Markov theory, defined to the first order, may be suspect.

Nevertheless, it has been established from the study of the Homb & Vik procedure that $\sigma_{Hs|Hs}$ increases with the threshold level of Hs. Hence, lesser correlation between successive larger sea states can be anticipated since the linear correlation coefficient is inversely related to the variance. Therefore, the acceptability of the Markov model, at least at these higher levels of Hs, is likely to be enhanced.

The Markov model used in the context of storm modelling requires the identification of two states of the process Hs(t), namely that of exceedence and non exceedence of the level α . The transition probabilities (see Kimura, 1980 and Longuet-Higgins, 1984) associated with these two states can be represented as:

$$p_+ = \int_{\alpha}^{\infty} \int_{\alpha}^{\infty} p(Hs_{i+1}, Hs_i) dHs_i dHs_{i+1} / \int_{\alpha}^{\infty} \int_{\alpha}^{\infty} p(Hs_i, Hs_{i+1}) dHs_i dHs_{i+1}$$

$$p_- = \int_0^{\alpha} \int_0^{\alpha} p(Hs_{i+1}, Hs_i) dHs_i dHs_{i+1} / \int_0^{\alpha} \int_0^{\alpha} p(Hs_i, Hs_{i+1}) dHs_i dHs_{i+1} \dots (1.10)$$

Where $p(Hs_i, Hs_{i+1})$ represents the joint probability density function of successive sea states.

It can be shown that the probability of J_s sea states consecutively exceeding the level α is given by:

$$p(J_s) = p_+^{J_s-1} (1-p_+) \dots \dots \dots (1.11)$$

and it follows that the mean number of sea states exceeding α is:

$$J_s = \sum_1^{\infty} J_s \times p(J_s) = \frac{1}{(1-p_+)} \dots \dots \dots (1.12)$$

Similarly, the distribution of storm inter-arrivals can be formulated as:

$$p(J_i) = (1 - p_+)(1 - p_-)(p_+^{J_i-1} - p_-^{J_i-1}) / (p_+ - p_-) \dots\dots\dots(1.13)$$

and the mean number of sea states between storm inter-arrivals follows as:

$$J_i = \sum_2^{\infty} J_i x p(J_i) = \frac{1}{1-p_+} + \frac{1}{1-p_-} \dots\dots\dots(1.14)$$

The only problem remains to choose a suitable probability distribution to model $p(H_{s_i}, H_{s_{i+1}})$: An obvious choice may be the bi-variate Weibull distribution originally developed by Rice (1944, 1945) and Ulhebeck (1943) and applied more recently by Kimura (1981) to model the joint probability distribution of individual wave heights and periods, $p(H, T_z)$. However, it has been found that the conditional statistics of the observed $p(H_{s_i}, H_{s_{i+1}})$ is characteristically different from that inherent in bi-variate Weibull function (see Salih, 1986).

The use of the bi-variate Log-Normal probability distribution, used by Ochi (1987) to model the long-term joint distribution of H_s and average zero crossing periods has also been investigated; more accurate representation of the conditional probabilities is obtained than with bi-variate Weibull model. It must be noted, however, that this choice does not affect the relative merits of either the Log-Normal or Weibull functions to describe the marginal distribution of H_s , $p(H_s)$.

Using both of these bi-variate distributions, the average durations of storms are predicted from the Markov model and the results are presented in Table 1. Also included in this table are the corresponding estimates for the Houmb & Vik and the Gaussian transformation procedures to enable the direct comparison of the various models.

It is apparent that the Markov model consistently underestimates the average durations at the lower thresholds. This arises mainly from the fact that successive sea states are strongly correlated at these levels and thus the assumptions inherent in the Markov model are more severely violated. In line with this reasoning, the predictions become in closer agreement with observed averages towards the higher sea state levels. The accuracy of the Markov model can be of the same order, and occasionally marginally better, as that noted for the Houmb and Vik procedure.

This property renders the Markov model particularly useful for engineering applications where the synthesis of storm statistics at these higher thresholds can be of particular importance.

Furthermore, the Markov model enables the modelling of the distribution of storm durations without the need to invoke any extra assumptions. Figure 9 shows that the Markov predictions are in close agreement with the observed distributions for storms at higher thresholds.

Figure 9: Distribution of storm durations with predictions from Markov model.

1.4 STORM SHAPE DESCRIPTORS

The storm models discussed do not provide information regarding profiles and energy contents of the storm events. A variety of statistics can be utilised for describing the storm intensity or severity at given threshold level of sea state. A complete description of the probability distribution of H_s within the duration of the storm would be an ultimate solution. However, this is expected to be rather complex and difficult to test empirically. An alternative approach, that is of lesser complexity, would be to specify certain statistics that characterise the storm profile and from which the severity of the storm can be inferred.

It is considered that useful insight may be obtained by investigating the distributions of the peak H_s attained in a storm, (H_{s_p}), the mean H_s within the storm events, (\bar{H}_{s_g}), or the distribution of the root mean square H_s , ($\sqrt{\bar{H}_{s_g}^2}$). The latter statistic may be taken as a measure of mean sea state energy per unit time.

Figure 10 plots the probability distribution of peak H_s attained within the duration of a storm normalised by the threshold level α .

The predictions arising from the Gaussian transformation model are super-imposed on Figure 10.a. These are based on the expression for distribution of amplitudes in a wide-banded Gaussian process. The results are found to follow the observed behaviour quite reasonably. However, the match is far from exact and the discrepancy arises from certain assumptions associated with the theoretical model (principally that the theory relates to the description of all 'local' maxima whilst only storm 'global' peaks are of significance to this application).

The 2-parameter Weibull distribution has been found to accurately model the upper half of the distribution of H_{s_p} as can be noted from Figure 10.b.

Figure 10: Distribution of peak Hs within a storm.
(a) with predictions from the Gaussian transformation model
(b) with predictions from 2 parameter Weibull model

Figure 11 shows that the average Hs within the duration of a storm can be modelled accurately by a 2-parameter Weibull distribution. The use of other empirical distributions has also been assessed and established that the shifted exponential and Gamma distributions prove generally acceptable for this purpose.

The distribution of root mean square Hs within the storms can be used to provide information relating to the energy content of the storms. Using expressions from the linear wave theory it follows that:

Energy per unit surface area is proportional to $E[Hs^2]$

The results presented in Figure 12 point to the suitability of the 2-parameter Weibull model.

Figure 12: Distribution of root mean square H_s within a storm.

1.5 CONCLUSIONS

It is concluded, as judged from the Forties data, that the Gaussian transformation technique provides more accurate predictions of average durations of events than the other two models considered in this study. Furthermore, the potential of utilising the wealth of theory relating to Gaussian processes makes the technique a viable and indeed a superior alternative to the more traditional procedure proposed by Houmb and Vik.

The distribution of maxima of a wide band Gaussian process has been used to predict the distribution of storm peaks and the results of the present study point to the general validity of the resulting distribution particularly towards higher sea state thresholds.

However, further testing and calibration of the transformation model requires access to longer data bases that can be used, for example, to reliably extract the various, higher order, spectral parameters required for the definition of the distribution of durations.

The Markov model proves a useful tool in characterising the storm statistics at higher thresholds of sea states where both the average durations and the distribution of durations are reasonably well represented. It is important to note that the specification of the distribution of durations is an integral part of the Markov approach.

Similar studies are now required on data sets from differing locations and degrees of exposure in order to assess the site specific element of the storm models discussed herein.

1.6 ACKNOWLEDGMENTS

The wave data used in this study was supplied by BP and MAREX UK and the writers are most grateful for this support. The overall study was financed by the Marine Technology Programme of SERC and by Shell (UK). Funds to present the paper were made available by Dobbie and Partners.

CHAPTER 72

STATUS OF U.S.A. OCEAN ENERGY RECOVERY ACTIVITIES

Young C. Kim¹ Lloyd Lewis² Michael E. McCormick³ Larry S. Slotta⁴

Abstract

The state of the art of ocean energy recovery activity in the United States is described. The technologies discussed in the paper include extraction of wave, tidal, ocean thermal and ocean current energy. This status report is intended to provide a description of the various ocean energy technologies and an assessment of potential benefits that might be expected and potential problems that might be encountered.

Ocean Wave Energy Conversion

The present efforts in wave energy conversion in the United States are those at the Department of Energy (DOE), academic institutions and small specialized companies. Of the many types of wave energy extraction (McCormick, 1981), four are now under study and development in the U.S. These are the pneumatic wave energy converter, the contouring raft system, the tandem flap and two types of wave pump devices.

As illustrated in Figure 1, the pneumatic wave energy conversion system (PWECS) incorporates a wave-excited oscillating water column and a pneumatic turbine. The air above the water column is alternately compressed and expanded resulting in an alternating pressure difference across the turbine. A one-meter PWECS was tested in the second deployment of the KAIMEI in the Sea of Japan in 1985 (JAMSTEC, 1987). This effort was partially funded by DOE through the International Energy Agency. Improvements in capture chamber geometry and turbine performance are presently under study (McCormick, 1978; Richards and Weiskopf, 1987) at the U.S. Naval Academy. Efforts are also underway to improve the coupling of the counter-rotating rotors and incorporate a ring-generator into the design (Focas, 1981).

Figure 1. Schematic of a U.S. Naval Academy Pneumatic Wave Energy Conversion System

Figure 2. Sketch of a Sea Energy Corporation Contouring Raft Wave Energy Converter

The contouring-raft system is under development by the Sea Energy Corp. (Hagerman, 1987). The configuration is similar to that in Figure 2. Sea Energy is planning a test of a prototype 500 kw "one-raft" system utilizing a yoke attached to a mooring point and working through a hydraulic power system. Model testing of a 1:25 scale system is being performed for regular and random waves.

The Q Corporation (Division of Van Dresser Corporation), with partial DOE support, has developed the tandem flap wave energy converter illustrated in Figure 3 (Scher, 1985). Because of its ability to capture both incident and a portion of the transmitted wave energy (due to reflection from the second flap), it is significantly more efficient than a single flap device. A 10 kw version of the tandem flap design was tested in Lake Michigan in 1987 with uncertain results due to power takeoff and other component failures. Q Corp. plans further system modifications and both tank and field tests in the future (Q Corporation, 1985; Wilke, 1985).

Two point-absorber systems for wave energy extraction have been developed in the United States. Figure 4 illustrates the principal components of the DELBUOY system developed by ISTI-Deleware Inc. (Hicks, 1988; Pless, 1982). The system comprises a light weight, shallow draft cylindrical buoy driving a submerged, single-acting positive displacement pump tethered to the seafloor. The motions of the buoy open the pump for the pressure stroke with energy stored in the natural rubber return springs used to refill the system. Clean seawater is drawn into the pump through prefilters to remove particulate matter. The flow of pressurized seawater from the pump is rectified using check valves with pressure surges damped by hydraulic accumulation. The pump output is then passed through the reverse osmosis filter with approximately 80% of the flow returning to the sea and 20% as freshwater pumped to the shore through low pressure plastic pipelines. Full scale system tests were performed at the University of Puerto Rico in 1980-1985 and to date eight full-scale prototype have been built and tested. Future designs are expected to produce up to 12,000 gallons per day of freshwater.

A second point-absorber system is the Wave Energy Module (WEM) illustrated in Figure 5 developed by U.S. Wave Energy, Inc. (Hopke, 1985). The WEM consists of two parallel discs connected with hydraulic piston pumps. One disc is buoyant and rides on the ocean surface while the other (reaction plate) is suspended at a depth where motion due to waves is small. Hydraulic fluid is transferred from the piston pumps to a high-pressure accumulator and is then fed to a hydraulic motor connected to a generator. A 1:40 scale model was tested at Worcester Polytechnic Institute and University of Massachusetts in the 1970s. In 1979 1:10 scale model tests were performed on Lake Champlain. Future plans include a full scale prototype test in the North Atlantic by the Newfoundland Oceans Research and Development Corporation.

Tidal Energy Conversion

Plans for a large scale electrical powerplant using the tides were proposed as early as 1919 for the Passamaquoddy Bay in Maine and the Cobscook basins of the Bay of Fundy. Tidal power studies for DOE (Wayne, 1977; Main, 1980) focused on the development of sites in Passamaquoddy Bay in Maine and Cook Inlet in Alaska. From a life-cycle cost point of view, the Passamaquoddy project is attractive. The Half Moon Cove tidal project site is illustrated in Figure 6. The design is for a single pool, single effect extraction cycle. The tidal basin is initially filled by opening gates during a flood tide. At high tide, the gates are closed and some three hours later generation of energy begins. The average output would be 10.6 MW for 5 1/2 hours. Application for a preliminary Federal Energy Regulatory Commission permit was filed in 1987 for this project.

Ocean Thermal Energy Conversion

The potential areas of OTEC deployment in the vicinity of the U.S. include: Hawaii, Gulf of Mexico, and territories and possessions in the Caribbean and Pacific. The magnitude of the OTEC resource in these areas has been estimated to be 10^5 MW. The most suitable sites for early OTEC landbased deployment are steep sloped islands where the cold deep water is found close to shore. A temperature difference of about 20°C can be exploited to run a heat engine that produces electrical power. One principle employed for OTEC is the Rankine closed cycle illustrated in Figure 7. A working fluid such as ammonia boils at tropical sea surface temperatures (i.e., 26°C) in an evaporator and this ammonia vapor in turn drives a gas turbine which runs a generator. The vapor is then condensed to a liquid by cold seawater (i.e., 6°C) pumped from 800-1000 m ocean depths, and the cycle is repeated. In 1979 a small, floating OTEC plant known as Mini-OTEC (Figure 8) was deployed off the Island of Hawaii by Lockheed in conjunction with the State of Hawaii and Dillingham Corporation. Mini-OTEC produced about 50 kw (gross). Sea Solar Power Corporation has developed a 100 MW floating plant closed cycle OTEC concept (Sea Solar Power, 1987) as illustrated in Figure 9. With a depth and length of 63 and 120 m respectively, the semi-submersible spar design would weigh about 25,000 metric tons and support a 1,200 m long 8.5 m diameter cold water pipe. It would use Freon-22 as a working fluid. The net-power output and auxiliary power requirements would be met by four 34 MW turbogenerator sets. In a cost-shared effort by Ocean Thermal Corporation, DOE and the State of Hawaii, a 40 MW pilot plant was designed in two phases. This plant is illustrated schematically in Figure 10 (OTC, 1984). The status of these projects is uncertain because of current low oil prices and the projected high initial capital cost for the OTEC plants.

Another OTEC power cycle currently under investigation by DOE is the open or Claude cycle as illustrated in Figure 11. In this concept, seawater itself can be considered the working fluid. After initial

deaeration to extract noncondensable gases, warm seawater is flash evaporated in a vacuum chamber. Desalinated water vapor drives a steam turbine which in turn drives a generator. The water vapor is then either condensed in a direct contact condenser and discharged to the sea, or condensed with a surface condenser producing desalinated water as a byproduct. The latter feature is particularly attractive in arid tropical islands. A 165 kw open cycle OTEC experiment is planned to be conducted through a cost-shared project between DOE and the Pacific International Center for High Technology Research at the Natural Energy Laboratory of Hawaii, Kailua-Kona, Hawaii (Lewis, 1987). After a series of open cycle component evaluations (presently underway), an apparatus will be constructed and used to validate system performance predictions, identify technical issues and obtain data scalable to future commercial size plants. These experiments will be supported by an upgraded seawater supply system recently installed at the site (Lewis, 1988). This system included the installation of a 1.0 m diameter cold-water pipe capable of delivering 840 l/s (410 l/s to the OTEC facility, 430 l/s to State mariculture projects). The pipe represented the largest diameter, longest (2,060 m) pipe tranversing the steepest slopes ever spanned.

Ocean Current Energy Conversion

In waters adjacent to the United States, the significant ocean current resource is limited to the Florida Current and the Gulf Stream off the southeast coasts. Estimates of extractable energy from these sources vary from 10,000 to 25,000 MW. Two axial flow rotary current energy systems have been developed by U.S. companies. Aerovironment, Inc. with DOE support, developed a ducted hydraulic turbine called Coriolis for applications to the Florida Current (Figure 12). Rim suspended two stage counter rotating catenary rotors were designed to feed energy to rim-mounted generators. Completed research included hydraulic performance evaluation of the rotors, Analyses of anchoring and mooring configurations, and system economic studies (Lissaman, 1979).

A similar device was developed by the UEK Corporation and is illustrated in Figure 13 (Vauthier, 1984). Energy in a flowing stream is converted to mechanical energy by a two-stage turbine. A radial outflow stage is followed by an axial flow stage. The inlet flow is through a venturi-shaped 3.7 m diameter shroud which concentrates the flow energy. The entire mechanism is tethered by cables so as to be held in the current stream, or suspended below a support platform. The device has been tested in Chesapeake Bay by towing it behind a tugboat. The New York State Power Authority has purchased one unit for evaluation.

Conclusions

There is an abundant resource for ocean energy development in waters adjacent the United States and its territories. There is a high potential for extraction of energy in these waters from ocean waves, ocean thermal gradients, tides and ocean currents at selected sites. However, the existence of these resources does not imply immediately usable energy, since any device built to operate in these environments must be competitive with conventional land-based energy producing systems. Nevertheless, at some remote sites where conventional generation of power is relatively expensive, it is possible that an ocean energy source would provide economic power in the near future.

CHAPTER 73

LONG WAVES IN A SPANISH HARBOUR

Jose C. Santás López (*)
Gregorio Gómez Pina (**)

ABSTRACT

Short and Long Wave data recorded in Bilbao Harbour (Spain) have been analyzed in order to study water movements at the inner basins under storms conditions . Some of the trends obtained in prototype have been correlated with model test (regular long wave and irregular short waves) .

This harbour has been chosen for this research on the one hand because of the availability of the physical model and on the other hand because of the means provided by the Bilbao Port Authority

1.- INTRODUCTION

For a long time, there has been a great concern to know the behaviour of harbour basins with regard to long waves. These long waves can induce resonant effects in water bodies, and consequently, in moored ships. As a result, moored ship operations become much less efficient.

After the well known Longuet-Higgins' article, in 1964 (Longuet-Higgins, 1964), the amplitude of the long waves associated to wave grouping (β), was calculated. The expression for this magnitude was the following :

$$\beta = - 3 . g . a^2 / 2 . \omega^2 . h^2$$

Where : a = short wave amplitude ; $\omega = 2\pi/T$; T = wave period ;
h = water depth.

The wave set-down period (T_{SD}) corresponds to the wave grouping, being the former a function of the wave grouping grade and the wave peak period (T_{P}). The experimental evaluation of T_{SD} can be done in different ways : based in the number of waves in a group (Sand, 1982 a), from the SIWEH spectrum (Funke & Mansard, 1980), and also, as a mean value of the up-zero crossing period, obtained from the SIWEH spectrum T_{Z} (SIWEH) (Iwagaki, 1986).

This set-down wave is feeded by a second order mechanism from the short wave, in different ways (Bowers, 1977). In a harbour, this long wave will be as a bounded long wave (BLW), as a free long wave produced by the energetic imbalance at the harbour entrance, due to water

depth differences (FLW) , and as caused by wave breaking phenomena on a beach , located near a harbour , such as surf-beats and edge waves.

The resulting long wave can be in resonance with the different harbour basins if T_{B} is close to the natural period of the basins, giving rise to resonant amplifications.

The BLW has been widely studied and its parameters have been correlated with waves characteristics outside the harbour, for both unidirectional and directional waves, having a kind of energy spreading D_0 for the latter (Sand,1982 a, and 1982 b). An application of the BLW parameters was carried out for Sines Harbour by Vis et al, 1985.

This piece of work shows the results obtained in Bilbao Harbour where the BLW, FLW, and resonant amplifications were simultaneously detected under severe storm conditions. Regular long wave model tests were carried out to characterize harbour resonant responses. Also, irregular wave model tests were performed to compare trends in the prototype and model, in regard to long wave energy transfer outside and inside harbour basins.

2.- FIELD DATA ANALYSIS

Waves outside the harbour were recorded in a Datawell Waverider , located at a water depth of $h=50$ m (Fig.1). The signal transmitted by the buoy is collected at a station where it is recorded every 1 ó 3 hours, depending on whether there is an "alarm signal" or not (wave conditions such as $H_m > 4$ m., and $T_m > 16$ seg). The recording equipment consists of a HP-86 computer. The 5,000 data of each record are stored on a hard disk ($\Delta t = 0.5$ seg), transferred later to a moveable disk, and sent to the CEPYC, in Madrid. Sampling characteristics were chosen after studying the stationary and representative conditions of the calculated statistical and spectral

Fig 1: Position of measurement systems : Outside Waverider (1) ; "Morro" Waverider (2) ; Meteorological Station (3) and Pressure Sensors (4a & 4b) .

parameters (A. Fernandez , 1988). A deefp description of this system is shown in Martinez , Santás and Sanz , 1988 .

Long waves were registered by a pressure sensor, manufactured at the CEPYC, consisting of a differential thin film strain gauge, located in a watertight chamber, filled with silicone oil. The outer connexion was made by two openings in the sensor. One of these openings was feeded by a hydraulic filter to remove the tide long wave. The filter characteristics are : 6 dB high pass, crossing frequency $1/(6hr)$. The high frequency removing is done by the hydrodynamic attenuation of the water column in the sensor, installed at a water depth of 6 meters.

The information supplied by this pressure wave sensor was digitalized ($\Delta t = 2.5$ seg), using series of 4096 points, and recorded on other HP-86 system, transferred to a moveabl disk system later, and sent to the CEPYC, in Madrid.

The data analysis carried out later , based on the above mentioned information, is summed up bellow :

A) Waverider :

- Standard statistical parameter calculations
- Spectral calculations : FFT previous filtering ($T < 4$ seg, and $T > 25$ seg), and later smoothing (18 freedom degrees). The resulting time series will be called "*Outside Short Wave*" (OSW), and its corresponding spectrum $S(OSW)$.

- SIWEH calculations : long wave time series and spectrum , statistical analysis of typical values, estimation of T_w and grouping factor GF (Funke & Mansard, 1980). The SIWEH long wave will be called "*Outside Long Wave*" (OLW), and its corresponding spectrum $S(OLW)$.

B) Inner Wave gauge

- Surface wave recomposition, in amplitudes and phases, for the 10 min. $> T > 10$ sec. band, using the hydrodynamic wave attenuation factor K, given as :

$$K = \cosh (k.h) / \cosh (k.b)$$

where h = instantaneous water depth ; k = wave number ; b = distance from the bottom.

A frequency filter transference function was used to correct FFT data. Short and long wave band differentiation were defined in the following way :

Long wave : $1/(10 \text{ min}) < f < 0.04 \text{ Hz}$ (ILW)

Short wave : $1/(35 \text{ seg}) < f < 0.1 \text{ Hz}$ (ISW)

Typical statistical parameter calculations, for both time series, called "*Inside Long Wave*" (ILW), and "*Inside Short Wave*" (ISW) were made

Spectrum calculations for both time series with a previous Bingham smoothing, and a later Bartlett smoothing . The number of freedom degrees for ISW and ILW were 30 and 18, respectively.

2.1.- PROTOTYPE WAVE DATA STORAGE

Wave data storage began in March, 1986. The long wave pressure gauge was initially placed in position 4a (Figure 1), changing this position to 4b, in March 87, where it is still placed.

It was considered interesting to analyze the data only where long wave height was higher than 10 cms. The storms analyzed corresponded to the following days :

Position 4a : a) March 24-27, 1986
 Position 4b : b) April 20-21, 1987; c) September 4-5, 1987 ;
 d) January 22-26, 1988; e) January 30-February 12, 1988; f) March 16-17, 1988.

Figure 2 shows the time series for $H(z,s)$, corresponding to the Waverider (OSW), the inside short wave (ISW), and the inside long wave (ILW) for the stage a).

Fig. 2 : Wave Time Series $H(z,s)$: (——) Outside Short Wave (OSW), (----) Inside Short Wave (ISW), (.....) Inside Long Wave (ILW) . Data from 1.23.1988 to 2.17.1988 .

3.- RESULTS OBTAINED FROM PROTOTYPE MEASUREMENTS

First of all the short wave data OSW and ISW were correlated and compared. Two interesting aspects were found :

-The correlation between significant wave heights $H(z,s)$ inside (ISW), and outside (OSW) was in the range of 8 and 13% (fig. 3a), depending on the wave period.

- The significant and mean wave periods $T(z,s)$, and $T(z)$ have a small increment, between 7% and 9%. This fact is also found for the peak period T_p (Fig. 3b).

Fig. 3 : Comparison of Statistical Results between ISW and OSW
 3a) : $T(z,s)$; 3b) : $H(z,s)$.

As it will be explained later, similar trends appear in the physical model. Moreover, the values obtained for wave agitation coefficient inside the harbour, from both mathematical and physical models, appear to be within the above mentioned range for $H(z,s)$.

In regard to the long wave measured (ILW) inside the harbour and the short wave outside it (OSW), the main findings are as follows :

- The correlation between $H(z,s)$, (OSW), and (ILW) depends very much on the measurement area, which is indicative of some resonant mechanism. For location 4a (Fig.1) this correlation was found to be

$$H(z,s) (ILW) = 1.586 \cdot 10^{-3} \cdot [(H.T) (OSW) / h]$$

This kind of correlation fits better than the quadratic one used in Sand's, with data obtained from the stage a). However, for position b), which is more favorable for resonant effects due to its basin location, the correlation was found to be (with $r^2 = 0.8050$) :

$$H(z,s) (ILW) = 0,0732 + 4,841 \cdot 10^{-5} \cdot [(H.T)^2 (z,s) (OSW)] / h$$

Whereas for a best fit of (H,T) , the following formula is obtained ($r^2 = 0.72$) :

$$H(z,s) (ILW) = - 0.1177 + 6,319 \cdot 10^{-3} \cdot [(H.T) (z,s) (OSW)] / h$$

This last expression shows a degree of five times better for position 4a than for 4b (Fig. 4a and 4b). This explains a resonant effect for the long wave energy.

The unexpected fact that the quadratic expression for (H,T) is not clearly accomplished, could be explained by considering an

Fig. 4.- Correlation between $H(z,s)$ (ILW) and the Product $(H * T(z,s) (OSW))^2$: 4a) Lineal Fitting. 4b) Quadratic Fitting

amplification of the set-down proportional to H , instead to H^2 , in the inner harbour area. This amplification is due to an attenuation of the amplification factor caused by flow separation at the harbour entrance (Bowers, 1977).

The results calculated from the ILW, OLV, and SIWEH waves, obtained from the outside wave record, have also been correlated.

It was expected to obtain characteristic values of the number of waves in a group $(Df/f(p))$, taking into account the grouping factor GF. These values would allow to evaluate the transfer function G_{nm} between the short waves and the long set-down wave. However, the authors were not able to find a good correlation between the parameters GF and $(Df/f(p))$

The comparison between the values of $T(z)$ (SIWEH) or $T(z)$ (OLW) with $T(z)$ (OSW) has not given a high level of correlation. There seems to be a tendency to show increasing values towards the storm peak, and then decreasing slowly. The correlation between $T(z)$ (OLW) and Tz (OSW) was found to be somehow better in the following way :

$$Tz(\text{SIWEH}) = 6.6 \cdot T(z,s) (\text{OSW}) ; R^2 = 0.42$$

This expression is close to the value of the parameter $fp/Df = 5$, as found in Sedivy (Sand, 1982 a).

However, a certain value was systematically found for Tc (SIWEH) covering the range of 40-70 seg, coincident with the second spectral peak interval.

Fig.5.- Energy Spectra : A) SIWEH for the Outside waves (OLW)
B) Inside Long Wave (ILW).

When the SIWEH was smoothed by using a nine bands moveable rectangular window, the first spectral peak showed within the 250-350 sec. range, with other peaks within the ranges of 100-150 sec, and 40-50 sec. These results might indicate the existence of a main grouping period for the set-down, around the 40-50 secs, together with higher groupings, related to the subharmonics, being the latter responsible for the most important energy peaks in the SIWEH. Thus, the set-down should be understood as a wave family which is able to cause harbour resonance for some characteristic periods.

The ILW spectra show a well determined structure, with the maximum spectral peak in between 280 and 366 secs, and other peaks which only appear under storm conditions, around 40 and 180 seconds, respectively (fig.5a)

4.- MODEL TESTS

Different model tests were carried out for Bilbao Harbour (with regular and irregular waves, and also with moored ships). Some aspects of interest, related to the above mentioned long wave analysis performed in prototype, are presented hereafter. An undistorted scale 1:150 was used.

4.1.- REGULAR LONG WAVE MODEL TESTS

The purpose of these tests was to obtain a broad and detailed information of the resonant behaviour of the different harbour basins. The wave period range tested was from $30 \text{ s.} < T < 300 \text{ s.}$

4.1.2.- METHODOLOGY

The two main basins were filled with fluorescent cork spheres in order to observe the general way of oscillation of the two basins, for each exciting wave period. Maximum horizontal and transversal peak to peak water displacements, near the berthing places, were measured in detail, for the outer and inner harbour basins. Also, the existence of vortexes was remarked. Additionally, surface water displacements were measured in other points of interest alongside the berthing places. A very detailed information on the behaviour of the two basins was elaborated, remarking the bollard numbers at which characteristic water displacements were observed.

It should be remarked that, although wave periods were calibrated, wave heights were estimated visually. Therefore, the measurements of water surface displacements should not be understood quantitatively, since long waves could not be defined exactly by any known characteristic parameter such as the Ursell parameter.

4.1.3.- ANALYSIS OF RESULTS

The results were analyzed in two ways :

A) Representing in a plan view of the harbour (Fig.6A) the observed displacements in front of their corresponding bollards (crossing bars), together with the interpolated displacements in the bollards where no measurements were taken (white bars). Even though the spatial amplitude displacement distribution is sinusoidal, a linear distribution was adopted for comparative purposes. (Figs. 6b and c). The theoretical positions of nodes (χ_0 : main; χ_1 : first; χ_2 : second) were also indicated in the aforementioned figures, for each exciting wave period, using the simplifcative formulations for rectangular basins.

In regard to the use of the above mentioned simplifcative assumptions for rectangular basins, the following conclusions were drawn, after analyzing the behaviour of the two basins in the present physical model:

- The inclination of the quay called "Muelle Adosado", located at the end of the outer basin, induces a reflection of the standing wave, which makes the inclined basin behave in a different way than a rectangular one. Two interesting aspects should be pointed out :

- The antinode does not clearly appear in the vertical wall, at the basin end, due to the existence of horizontal water displacements in the direction of the inclined quay, caused by the above mentioned reflective effect of the standing wave.

- The section reduction at the change of alignment, in the inner main basin, causes an increment of the horizontal velocities of the standing wave. This effect is increased by the relative closeness of the first oscillating node.

B) Representing the maximum horizontal displacements (peak to peak) against the exciting wave periods (within the range of 30-300 secs), for the two main harbour basins.

Exciting Wave Periods.

4.1.4.- MODEL TEST CONCLUSIONS

After analyzing the figures shown in A), the following conclusions were obtained, related to the behaviour of the two harbour basins.

Outer Harbour Basin (Fig.6b)

It can be seen, from the figures, that the oscillatory displacement amplitude distribution looks like one corresponding to a standing or quasi-standing wave, with maximum displacements located near the node.

The "theoretical" resonant period of the basin was found in the range of 200-235 seg., depending on the oscillating length adopted (from the center of the Adosado Quay, or from the end). This range could be extended because of the longer wave standing trajectories caused by the reflection in the inclined pier at the bottom of the basin.

The above mentioned long wave reflective phenomenon was also shown in the model tests, by the transversal displacements experimented in the Cara Norte Quay, specially in bollard 5 (see bollard plan).

Another point to be remarked is the higher displacements found at the Princesa de España Quay with respect to its opposite one (Cara

Morte). Horizontal displacements up to 75 meters were measured at the Princesa de España Quay (bollard 3, near the entrance). Also, a drift displacement of 45 m. was observed in that bollard.

Inner Harbour Basin (Fig.6c)

The movements observed at the inner basin are significantly smaller than those found at the outer basin, and they are also distributed more uniformly.

The largest displacements are found at the change of alignment in the inner basin. The reasons for this could be as follows :

- The oscillation node is close to this area.
- This change of alignment is coincident with a reduction of the transversal section of this basin, which causes an acceleration of the confined mass of water.
- The antinode appears to be located at the end of the basin, which does not occur at the outer basin.

After analyzing the figures explained in B) (Fig.7), the following conclusions are drawn :

The Princesa de España Quay seems to be very sensitive to small wave period increments. For instance, for the range of $T = 200-260$ secs., the horizontal water displacement shifts from a value of 6 m., to the maximum one of 75 m., and then decreases down to 30 m., for the range of $T = 260-280$ secs, increasing again up to a new maximum (52.5 m.), for $T = 280-300$ secs., showing a decreasing trend after it.

The outer basin shows two distinctive peaks for its longitudinal oscillation, for the two parallel quays (Princesa de España and Cara Norte). The first peak is located near $T = 150$ secs., and the second peak around $T = 240-260$ secs. This second peak induces the largest water displacement (about five times more).

The outer and inner basins show similar trends in longitudinal oscillations (two distinctive peaks), although they both differ considerably in the oscillation amplitudes, as it was already explained.

The position of the main oscillating node seems to be a significant parameter for the way in which longitudinal water oscillations occur at the two parallel piers. The more symmetrical location of the main node at the inner basin, due to the lower inclination of the quay at the end, makes the two parallel piers (Cara Sur and Reina Victoria) oscillate in a very similar way.

The transversal water movements of the two basins are very small compared to the longitudinal ones.

4.2.- IRREGULAR WAVE MODEL TESTS

After analyzing wave spectra at different harbour areas (Fig.6a), energy transfer was found from the main peak period ($T_p = 17$ secs.) towards much higher periods in the range of 103-310 secs. The fact

that the maximum basin amplifications in the regular wave model tests are found around wave peak periods of 150 and 260 secs, could establish the existence of some kind of resonant effect, around these periods, when irregular waves are used in the model.

It should be remarked that the spectral analysis carried out in the model was based on 512 points, which only allow to know the range of wave energy transference, without clearly distinguishing the peak periods for the long wave. At the present, a more detailed wave spectral analysis (4096 points) is being performed at the CEPYC (Iribarren et al) to distinguish the spectral peaks much better.

Fig. 8.- Example of Wave Energy Spectra Obtained in the Physical Model:
 a) Outside Waves (P_1); b) Same for Santurce Entrance (P_2); c) Outer Basin Entrance (P_3); d) Inner Basin Entrance (P_4). (Points shown in Fig.6A; max. freq. 2 Hz).

5.- DISCUSSION

The set-down amplitude has been parametrized by Sand (1982) by means of the transfer function $G_{nm}(D\theta).h$. For the case of deep or shallow water, the following asymptotic expressions for unidirectional waves ($D\theta = 0$) were found, function of the P parameter ($P = \text{SQR}(h/g)/T_p$):

$$\begin{aligned}
 P < .15 \text{ ---- } G_{nm}(D\theta=0).h &= (3/8.\pi^2) . P^{-2} . (1/(1+Df/fp)) \\
 P > 3 \text{ ---- } " &.h = 2 . \pi^2 . P^2 . (Df/fp) . (2+(Df/fp))
 \end{aligned}$$

For the case of directional waves ($D\theta \neq 0$), the solutions were presented in a graphic way.

The considered depth h corresponds to the measurement point of the incident waves. However, this transference function grows when decreasing water depth, in the following way :

$$G_{rim} (D\theta = 0) \cdot h \propto (1 / k^2 \cdot h^3)$$

This implies that set-down will grow with water depth decrease. Thus, an increase in the mean water level will be expected in the recordings. Comparisons between the results obtained from the waverider and those from the Bilbao Port in this zone showed that such a variation could not be detected as far as the entrance of the inner basin, located at 18 m. water depth. Furthermore, the results from the physical model testes seemed to confirm this fact, the peak not appearing in the range of 40-60 secs., up to this point.

The above mentioned findings made possible to estimate the wave set-down amplitude for a water depth of 22 m, considered as a mean value for the outer zone.

As for directional waves, a mean value of $D\theta = 27^\circ$ was obtained, for a directional buoy (wavescan), located outside the harbour ($h \approx 300$ m.), during December-87 (Arribas and Morón, 1988). A value of $D\theta = 20^\circ$ was adopted, corresponding to the tabulated results showed below. The number of waves in a group may be of 5, as considered by Sand, whose value is in the order of the data (item 3). The wave peak periods, under storm conditions, are within the range of 12 and 20 secs., and the P parameter results : $.075 < P < .125$, which corresponds to shallow water conditions.

In order to evaluate the set-down amplitude, $A_s = A_m$ was taken which is equivalent to consider two wave amplitudes very close in frequency, and thus creating a wave energy train equivalent to the original one, having H_m as a significant wave height. Under these conditions, the values obtained for β/H_m^2 were as follows :

	$\beta = (G_{rim} (D\theta=0) \cdot h) * H_m^2 / 16 h$				
<u>Dθ</u>	<u>TP=12</u>	<u>TP=15</u>	<u>TP=18</u>	<u>TP=20</u>	
0	.0068	.0106	.0153	.0189	
20	.0018	.0020	.0022	.0023	
P =	.124	.0998	.083	.075	

When these values are referred to real values measured in prototype, the results are as follows :

<u>Date</u>		<u>O.S.W.</u>		<u>β</u>		<u>I.L.W.</u>	
<u>Day / Time</u>	<u>Hs</u>	<u>TP</u>	<u>Dθ=0</u>	<u>Dθ=20</u>	<u>Hs(ILW)</u>	<u>Position</u>	
4.9.87 14	2.57	15.0	.07	.013	.016	4b	
10.2.88 11	5.81	14.4	.36	.068	.72	4b	
25.3.86 3	6.5	15.0	.44	.080	.12	4a	

For small wave heights, $H_m(OSW) < 1.5$ m., in position 4a, wave heights in the range of 0.02 were detected almost continuously, probably corresponding to the case of a free wave generated by the change in water depth at the harbour entrance. Taking this fact into account, the measured wave heights ILW obtained in position 4b are higher than the calculated set-down, and they must correspond to resonant amplifications induced by the set-down. Wave spectra obtained from the physical model show similar tendencies.

If wave spectra at the entrance of Basins 1 and 2 are compared to the wave spectrum considered as "exciter" (Figs. 6a and 8), the peak corresponding to the long wave appears in the range of 50-250 secs., growing towards the end of the basins.

Therefore, it seems possible to confirm the hypothesis that the set-down is amplified by resonant oscillations, although not in its principal mode, but in the subharmonic ones whose periods are close to the natural periods of the basins studied. That is way the peak period of waves at the end of the basins grows simultaneously with the decrease of the total energy, acting the set-down, because of its second order characteristics, as an energy transfer.

6.- CONCLUSIONS

1) The mechanism of set-down comes out as a wave packet whose frequency distribution corresponds approximately with that adopted by the SIWEH spectrum outside the harbour, being able to generate resonancies according to its frequency band.

2) Set-down generates an energy transfer from the usual wave frequencies towards lower frequencies, producing an increase of the peak period, altogether with a general decrease of the total energy. In the present case, a decrease around 7-9% for T_c , coincident with a decrease for H_m of 90-92%. has been detected

3) Calculations of statistical parameters carried out from the SIWEH have only permitted to obtain an imprecise idea of the number of waves in a group, as well as of the main set-down period, from the $T(z,s)$ and T_c parameters, respectively.

4) SIWEH spectrum shows approximately the existence of several waves, corresponding with the set-down subharmonics. Furthermore, SIWEH spectra peaks coincide with bands of accused energy detected for Long Wave spectra analyzed at the end of the basins, thus being the probable origin of resonances depending on the natural periods of the basins.

5) The resonant modes detected in the physical model, using regular waves, show in a semiquantitative way, the existence of amplitudes of a certain importance, for the horizontal water displacements in the outer harbour basin whereas the inner basin is less susceptible to resonances.

6) The model tests with regular waves have allowed to study the behaviour of the outer and inner harbour basins, analyzing the response of those basins with respect to a large range of wave exciting periods. In the neighbourhood of the natural modes of oscillation, the amplification grows rapidly and resonant effects may appear, even with energies not being exactly in the natural frequency of oscillation. The non strictly regular geometry of the basins fosters the lack of a well determined frequency of oscillation but a relatively narrow frequency band where resonant effects could be developed under severe storm conditions.

7.- ACKNOWLEDGEMENTS

The authors are indebted to Mr.J. Lozano and Mr.J.R. Iribarren for their help during the analysis of the results of the model tests with irregular waves. Mr.M. Seillan and Mr.R. Amarilla, Argentinian scholarship holders at the CEPYC, collaborated in the studies related to regular waves, and Ph.Dr.Mr. A. Fernández, Miss.C.Benito and Mr.F. Muñoz made an important collaboration in the field data analysis. The authors greatly appreciate the cooperation as well as the means provided by the Bilbao Port Authority .

CHAPTER 74

Dynamic Wave Setup

Jen-Men Lo, M. ASCE¹

Abstract

The wave setup for a given wave spectrum was re-evaluated with the radiation stress term including the low-frequency terms. This setup which is referred to here as "dynamic wave setup", was compared with the steady setup, which is generated by including only the non-periodic radiation stress terms.

The results of the study showed that the dynamic wave setup is greater than the steady wave setup, sometimes almost double its value. Therefore, the dynamic wave setup is important for engineering applications, particularly in the study of storm surges and coastal engineering problems.

Introduction

Longuet-Higgins and Stewart (1963) showed theoretically from their concept of radiation stress, and Bowen et al. (1968) verified it in the laboratory, that there is a water level setdown outside the surf zone followed by a water level setup within the surf zone because of the presence of the wave motion.

Longuet-Higgins and Stewart (1963) considered only the monochromatic waves, but Collins (1972), Battjes (1974), and Wu et al. (1978) re-evaluated wave setup by considering the radiation stress for a given spectrum.

The radiation stress derived for a wave spectrum should include the interaction between any wave component and itself as well as the interaction between any wave component and other wave components. However, the studies carried out by Collins (1972), Battjes (1974), and Wu et al. (1978) considered only the self-interaction terms.

Lo (1981) derived the radiation stress term for any given wave spectrum. In this derivation both non-periodic and long-period oscillation (low frequency) terms were included. The low-frequency terms were generated from the non-linear transfer of energy of the phase difference between different wave components.

The purpose of this study is to re-evaluate wave setup for a given wave spectrum with the radiation stress term including the low-frequency terms. This setup which is referred to here as "dynamic wave setup" was compared with the

¹ Research Scientist, Kuwait Institute for Scientific Research, Hydraulics and Coastal Engineering Group, P. O. Box 24885, 13109, Safat, Kuwait.

steady wave setup, which was generated by including only the non-periodic radiation stress terms.

Governing Equations for the Surf Beat Wave on a Sloping Bottom

The motion is considered irrotational and the fluid incompressible. Integrating the continuity and momentum equations from the bottom, $Z = -h$, to the free surface, $Z = \eta$ (water surface displacement), imposing the Leibnitz rule, and substituting the no-flow bottom boundary condition (BBC), the kinematic free surface boundary condition (KFSBC), and applying the time average over one incoming wave period one can obtain the governing equations for the sloping bottom surf beat wave. For convenience, only a uniform bottom slope will be considered.

Leibnitz Rule. The Leibnitz rule of differentiation will be used to obtain a derivative from within an integral. It is stated as follows

$$\int_{\alpha(x)}^{\beta(x)} \frac{\partial f(x,z)}{\partial x} dz = \frac{\partial}{\partial x} \int_{\alpha(x)}^{\beta(x)} f(x,z) dz - f(\beta,z) \frac{\partial \beta(x)}{\partial x} + f(\alpha,z) \frac{\partial \alpha(x)}{\partial x} \quad (1)$$

where $f(x, z)$ is any function; x is a variable of integration; z is a dummy variable of integration; α and β are limits of integration.

Boundary Conditions. At the bottom, $Z = -h$, a no-flow boundary condition exists. In vector form

$$\vec{V} \cdot \vec{n} = 0 \quad (2)$$

where

$$\vec{V} = u\vec{i} + v\vec{j} + w\vec{k} \quad (3)$$

$$\vec{n} = \frac{\left(\frac{\partial h}{\partial x} \vec{i} + \frac{\partial h}{\partial y} \vec{j} + \vec{k} \right)}{\sqrt{\left(\frac{\partial h}{\partial x} \right)^2 + \left(\frac{\partial h}{\partial y} \right)^2 + 1}} \quad (4)$$

(Unit vector normal to the bottom)

where $\vec{i}, \vec{j}, \vec{k}$ are unit vectors in the x, y, z directions; \vec{V} is the velocity vector and u, v, w are the x, y and z components of the velocity vector. BBC can be rewritten as

$$u \frac{\partial h}{\partial x} + v \frac{\partial h}{\partial y} + w = 0, \quad \text{at } z = -h(x,y)$$

At the free surface, the vertical velocity (w) must account for the changes in the instantaneous water surface (η)

$$w = \frac{D\eta}{Dt} = \frac{\partial\eta}{\partial t} + u \frac{\partial\eta}{\partial x} + v \frac{\partial\eta}{\partial y}, \quad \text{at } z = \eta \quad (5)$$

This is the KFSBC.

Continuity Equation. The general form of the continuity equation in three dimensions is

$$\frac{\partial\rho}{\partial t} + \frac{\partial\rho u}{\partial x} + \frac{\partial\rho v}{\partial y} + \frac{\partial\rho w}{\partial z} = 0 \quad (6)$$

Integrating each term with respect to depth between $Z = -h$ and $Z = \eta$, and imposing the Leibnitz Rule

$$\begin{aligned} \frac{\partial}{\partial t} \int_{-h}^{\eta} \rho dz - \rho_{\eta} \frac{\partial\eta}{\partial t} - \rho_{-h} \frac{\partial h}{\partial t} + \frac{\partial}{\partial x} \int_{-h}^{\eta} \rho u dz - (\rho u)_{\eta} \frac{\partial\eta}{\partial x} - (\rho u)_{-h} \frac{\partial h}{\partial x} + \\ \frac{\partial}{\partial y} \int_{-h}^{\eta} \rho v dz - (\rho v)_{\eta} \frac{\partial\eta}{\partial y} - (\rho v)_{-h} \frac{\partial h}{\partial y} + (\rho w)_{\eta} - (\rho w)_{-h} = 0 \end{aligned} \quad (7)$$

Invoking the boundary conditions BBC and KFSBC, the above equation simplifies to

$$\frac{\partial}{\partial t} \int_{-h}^{\eta} \rho dz - \rho_{-h} \frac{\partial h}{\partial t} + \frac{\partial}{\partial x} \int_{-h}^{\eta} \rho u dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} \rho v dz = 0 \quad (8)$$

Considering the depth (relative to still water level) as constant in time, and the problem as two-dimensional (no dependency on the y - direction), the above equation becomes:

$$\frac{\partial}{\partial t} \int_{-h}^{\eta} \rho dz + \frac{\partial}{\partial x} \int_{-h}^{\eta} \rho u dz = 0 \quad (9)$$

Consider the horizontal water particle velocity as the superposition of two components,

$$u = u_I + u_s \quad (10)$$

where

u_I = the horizontal water particle velocity of the incoming wave

u_s = the horizontal water particle velocity of the surf beat wave which is uniform over depth since the water depth is relatively shallow in comparison to the surf beat wave length.

Thus, for a fluid of constant density ρ , the continuity equation becomes

$$\frac{\partial}{\partial t}(h + \eta) + \frac{\partial}{\partial x}u_s(h + \eta) + \frac{\partial}{\partial x} \int_{-h}^{\eta} u_I dz = 0 \quad (11)$$

The time averages are defined

$$\bar{F} = \frac{1}{T} \int_0^T F dt \quad (12)$$

then

$$F_s = \bar{F}_s = \frac{1}{T} \int_0^T F_s dt$$

where T is the incoming wave period, and F_s represents a general surf beat variable. Time averaging the continuity equation, we obtain

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x}u_s(h + \bar{\eta}) + \overline{\left(\frac{\partial}{\partial x} \int_{-h}^{\eta} u_I dz\right)} = 0 \quad (13)$$

where $\bar{\eta} = \eta_s$ is the water surface displacement of the surf beat wave. The time-averaged water surface displacement of the incoming wave, $\bar{\eta}_I$, is zero.

Following the definitions of Phillips (1966) for the total flux

$$M_x = \overline{\int_{-h}^{\eta} \rho u_I dz} \quad (14)$$

and for the mean transport velocity

$$u_I = \frac{M_x}{\rho(h + \eta)} \quad (15)$$

The continuity equation can be written as

$$\frac{\partial \eta_s}{\partial t} + \frac{\partial}{\partial x}(u_s + u_I)(h + \eta_s) + \frac{\partial}{\partial x}(\overline{u_I \eta_I})_{z=0} = 0 \quad (16)$$

where

$$\frac{\partial}{\partial x}(u_s + u_I)\eta_s \ll \frac{\partial \eta_s}{\partial t}$$

The final result is then

$$\frac{\partial \eta_s}{\partial t} + \frac{\partial}{\partial x} (u_s + u_I)h + \frac{\partial}{\partial x} (\overline{u_I \eta_I})_{z=0} = 0 \quad (17)$$

Equation of Motion. Without considering the shear stresses, the general form of the equations of motion are:

x Direction.

$$\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial uv}{\partial y} + \frac{\partial uw}{\partial z} = \frac{1}{\rho} \frac{\partial P}{\partial x} \quad (18)$$

z Direction.

$$\frac{\partial w}{\partial t} + \frac{\partial uw}{\partial x} + \frac{\partial vw}{\partial y} + \frac{\partial w^2}{\partial z} = -\frac{1}{\rho} \frac{\partial P}{\partial z} - g \quad (19)$$

where p = pressure, and g = gravitational constant.

Following the same procedure as outlined before the final equation of motion for the case of two dimensional sloping bottom surf beat wave becomes

$$\frac{\partial (u_s + \overline{u_I})h}{\partial t} = -gh \frac{\partial \eta_s}{\partial x} - \frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} - \frac{\partial}{\partial t} (\overline{u_I \eta_I})_{z=0} \quad (20)$$

where

$$S_{xx} = \rho \int_{-h}^0 (\overline{u_I^2 - w_I^2} dz) + \frac{1}{2} \rho g \overline{\eta^2} \quad (21)$$

It should be noted that the sloping bottom surf beat wave problem is governed by equation of motion (Eq. 20), and the continuity equation (Eq. 17).

Irregular Wave Conditions

The irregular sequence of linear waves can be represented as an infinite sum of simple harmonic waves

$$\eta(x, t) = \sum_n a_n \cos(k_n x - \sigma_n t + \epsilon_n) \quad (22)$$

where

$$a_n = \sqrt{2\rho_\eta(\sigma)\Delta\sigma}$$

$P_\eta(\sigma)$ = the energy density spectrum of the irregular sea, varying with wave angular frequency σ , and

ϵ_n = the phase angle (radians) for the n th wave component.

When small amplitude wave theory is used to estimate the flow regime in a wave system from the surface profile, the linear relationship between the surface profile and the velocity potential results in

$$\phi(x, z, t) = - \sum_n \frac{a_n g}{\sigma_n} \frac{\cosh k_n (h+z)}{\cosh k_n h} \sin(k_n x - \sigma_n t + \epsilon_n); \quad (23)$$

the dispersion relationship is given by

$$\sigma_n^2 = g k_n \tanh k_n h \quad (24)$$

also the horizontal and vertical water particle velocity components are given by

$$u(x, z, t) = \sum_n \frac{a_n k_n g}{\sigma_n} \frac{\cosh k_n (h+z)}{\cosh k_n h} \cos(k_n x - \sigma_n t + \epsilon_n) \quad (25)$$

and

$$w(x, z, t) = \sum_n \frac{a_n k_n g}{\sigma_n} \frac{\sinh k_n (h+z)}{\cosh k_n h} \sin(k_n x - \sigma_n t + \epsilon_n) \quad (26)$$

After some algebraic manipulation the following equations result:

$$\eta^2 = \sum_{n=1}^N a_n^2 \cos^2 \theta_n + \sum_{m=1}^{N-1} \sum_{n=m+1}^N a_m a_n [\cos(\theta_m - \theta_n) + \cos(\theta_m + \theta_n)], \quad (27)$$

$$u^2 = \sum_{n=1}^N A_n^2 \cos^2 \theta_n + \sum_{m=1}^{N-1} \sum_{n=m+1}^N A_m A_n [\cos(\theta_m - \theta_n) + \cos(\theta_m + \theta_n)], \quad (28)$$

$$w^2 = \sum_{n=1}^N B_n^2 \sin^2 \theta_n + \sum_{m=1}^{N-1} \sum_{n=m+1}^N B_m B_n [\cos(\theta_m - \theta_n) + \cos(\theta_m + \theta_n)] \quad (29)$$

where N is the total number of the wave components, and

$$\theta_n = k_n x - \sigma_n t + \epsilon_n$$

$$A_n = -a_n \sigma_n \frac{\cosh k_n(h+z)}{\sinh k_n h}$$

$$B_n = -a_n \sigma_n \frac{\sinh k_n(h+z)}{\sinh k_n h}$$

The sum of the phases are not considered for the surf beat wave problem, because they are in the high frequency region. Then

$$\begin{aligned} S_{xx} &= \frac{\rho}{z} \sum_{n=1}^N \frac{a_n^2 \sigma_n^2}{\sinh^2 k_n h} h + \frac{1}{4} \rho g \sum_{n=1}^N a_n^2 \\ &+ \rho \sum_{m=1}^{N-1} \sum_{n=m+1}^N \frac{a_m a_n \sigma_m \sigma_n \sinh(k_m - k_n)h}{(k_m - k_n) \sinh k_n h \sinh k_m h} \cos(\theta_m - \theta_n) \\ &+ \frac{\rho g}{z} \sum_{m=1}^{N-1} \sum_{n=m+1}^N a_m a_n \cos(\theta_m - \theta_n) \end{aligned} \tag{30}$$

and

$$\overline{(u_I \eta_I)}_{z=0} = \frac{1}{2} \sum_{m=1}^N \sum_{n=1}^N a_m a_n \sigma_n \frac{\cosh k_n h}{\sinh k_n h} \cos(\theta_m - \theta_n) \tag{31}$$

Method of Solutions

The governing equations are

1. Equation of Motion

$$\frac{\partial q}{\partial t} = -gh \frac{\partial \eta_s}{\partial x} - \frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} - \frac{\partial}{\partial t} \overline{(u_I \eta_I)}_{z=0} \tag{32}$$

2. Continuity Equation

$$\frac{\partial \eta_s}{\partial t} + \frac{\partial q}{\partial x} = - \frac{\partial}{\partial x} \overline{(u_I \eta_I)}_{z=0} \tag{33}$$

where

$$q = (u_s + u_l)h$$

The complete mathematical solution of these equations is complicated. However, these equations can be solved numerically by applying finite difference techniques to the method of characteristics. This procedure accounts for bottom slope (wave reflection) and the transient nature of the problem.

Due to the depth variations and associated changes in the slopes of the characteristic lines, the characteristic lines in the x - t plane form a curved network and the results require interpolation to give values on a regular rectangular grid system. This problem can be resolved through the introduction of the following dimensionless variables, which will transform the curved characteristics to straight lines:

$$\begin{aligned}
 1. \quad Y &= \frac{\sqrt{x}}{x_2} \\
 2. \quad t' &= \frac{t}{T} \\
 3. \quad Z &= \frac{\eta_s C_2 \sqrt{Y}}{U^2 T} \\
 4. \quad Q &= \frac{q}{U^2 T \sqrt{Y}} \\
 5. \quad r &= 1 - \sqrt{\frac{h_1}{h_2}} \\
 6. \quad F_1 &= \frac{1}{u^2} \left[\frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} + \frac{\partial}{\partial t} (u_l \eta_l)_{z=0} \right] \\
 7. \quad F_2 &= - \frac{C_2}{u^2} \left[\frac{\partial}{\partial x} (u_l \eta_l)_{z=0} \right]
 \end{aligned} \tag{34}$$

where

$$T = (x_2 - x_1) / \bar{C}$$

$$\bar{C} = (C_1 + C_2) / z$$

$$C_1 = \sqrt{g h_1} = \sqrt{g m x_1}$$

$$C_2 = \sqrt{g h_2} = \sqrt{g m x_2}$$

$$U = 0.22815 \text{ gm } h_{b(max)}$$

x_1 is the distance from shore ($x = 0$) to the wall boundary; x_2 is the distance from shore to the offshore boundary, and m is the beach slope.

By using the above transformations, the equation of motion and continuity equation are rewritten in the form

$$\frac{\partial Q}{\partial t'} + \gamma \left[\frac{\partial z}{\partial Y} - \frac{z}{2Y} \right] = - \frac{F_1}{\sqrt{Y}} \quad (35)$$

$$\frac{\partial z}{\partial t'} + \gamma \left[\frac{\partial Q}{\partial Y} - \frac{Q}{2Y} \right] = - \frac{F_2}{\sqrt{Y}} \quad (36)$$

The sum of these equations gives

$$\frac{d(Q+z)}{dt'} = \frac{\gamma}{2Y} [z-Q] - \frac{F_1}{\sqrt{Y}} - F_2 \sqrt{Y} \quad \text{for } \gamma = \frac{dY}{dt'} \quad (37)$$

and the difference of these equations gives

$$\frac{d(Q-z)}{dt'} = \frac{\gamma}{2Y} [z+Q] - \frac{F_1}{\sqrt{Y}} + F_2 \sqrt{Y} \quad \text{for } \gamma = - \frac{dY}{dt'} \quad (38)$$

A path in the Y, t' plane having a constant slope $\pm\gamma$ is the characteristic line and the values of $Q \pm Z$ along such lines are in accordance with equations 37 and 38. These equations are solved by finite different methods.

1. *Boundary Condition.* At the shore, where the water depth equals zero, this is a singular point. For convenience, a wall will be assumed for the calculations, i.e., the no-flow boundary condition at the wall is $q = 0$. In deep water, the forcing function of the surf beat wave is very small. Therefore, the boundary condition at offshore is a radiative condition; the surf beat wave will propagate offshore and no surf beat wave will enter the system under consideration from offshore.
2. *Initial Condition.* The sloping bottom surf beat problem is a transient problem. The transient nature is due to the increase in the surf beat wave height during propagation toward shore under the action of the forcing function, S_{xx} . At time zero, no wave occurs on the water surface, then later an incoming wave group propagates from infinity to shore with a surf beat wave force at the speed of the incoming wave velocity due to the forcing function induced by the incoming wave.
3. *Changing Breaking Zone.* A spilling wave breaking was assumed in this model, the incoming wave breaking height and local depth are related by

$$a_b = kh$$

The value of k is constant. In this study, the constant k will be taken as 0.39 and the wave height in the surf zone will depend only on the water depth. For an irregular wave field, the location of wave breaking will vary with the water depth. Therefore, the wave breaking process occurs in an area instead of at only one location as the regular wave breaking process.

Comparison of the Steady Wave Setup with the Surf Beat Wave Simulation Model

A given deep water wave spectra and the surf beat wave simulation model is applied to compare the difference between the surf beat wave and the steady wave setup. Figure 1 shows the assumed deep water wave spectra. The width of the energy frequency band ϵ defined by Rice (1945) is equal to 0.16. The incoming wave periods range from 8 to 12 seconds, and ten wave components with equal frequency increment are selected from the given spectrum. The significant wave height is 4.76 ft. In the simulation model, the bottom slope is 0.02, the offshore boundary water depth is 80 ft and the shore boundary water depth is 1.2 ft. The time step is 1.383 s.

**SPECTRUM NO. 2
SIGNIFICANT WAVE HEIGHT = 4.76 FEET
WAVE PERIODS FROM 8 TO 12 SECONDS
WIDTH OF THE FREQUENCY BAND = 0.16**

Figure 1. Deep water incoming wave spectrum for the study of the correlation between the surf beat and the wave envelope.

Figure 2 presents the comparisons of the steady wave setup with the surf beat wave on the shore boundary, where the steady wave setup is calculated from

Figure 2. Comparison of the steady wave setup with the dynamic wave setup (simulated by using the wave spectrum in Figure 1).

$$\bar{\eta} = -\frac{K^2 h_b}{16} - \frac{\frac{3}{8} K^2}{1 + \frac{3}{8} K^2} (h_1 - h_b) \quad (39)$$

and h_1 is the water depth at the shore boundary, h_b is the wave breaking depth, K is a constant (here it is 0.78). It is clear that the steady setup and the surf beat wave are almost in phase; however, the crest of the surf beat wave is higher than the steady wave setup height. This setup due to the existence of the surf beat wave is referred to as the "dynamic wave setup", because it includes the contribution from both the non-periodic and low frequency radiation stress terms, and the steady wave setup is generated by including only the non-periodic radiation stress terms.

Conclusions

The results of the study showed that the dynamic wave setup is greater than the steady wave setup, sometimes almost double its value. This is due to the existence of the surf beat wave. Therefore, the dynamic wave setup is important for engineering applications, particularly in the study of storm surges and coastal engineering problems.

CHAPTER 75

Pore pressure induced by wind waves in sand bed

S.R. Massel * and L. Kaczmarek **

Abstract

The two projects (LUBIATOWO 79 and LUBIATOWO 86) were aimed at study pore pressure behaviour in natural sand bed in the coastal zone of the Baltic sea under the action of storm waves. During both projects, the wave induced pore pressures at the various levels in the sea bed were measured. The collected data were used to verify the applicability of the various theoretical approaches. In the conclusion, the range of the application of the particular analytical method is given.

1. Introduction

The problem of wave induced pressures and stresses in natural sea beds is important with regard to the design of foundations for various ocean and nearshore structures, such as gravity type breakwaters, offshore oil storage tanks and drilling rigs. The subject is also important when one considers the floatation of buried pipelines and the burial of rubble mounds by waves.

The wave-induced flow in a porous bed experiences a flow resistance and transmits forces, seepage forces, to the soil skeleton. From a hydrodynamic point of view the flow induced by waves in a porous bed is of interest since energy dissipation, i.e., wave attenuation, is associated with this flow. Early papers (Putnam, 1949; Reid and Kajiura, 1957; Liu, 1973; Moshagen and Tørum, 1975) have focused on a permeable sea bed with a fixed rigid grain skeleton. Moshagen and Tørum (1975) considered the wave-induced flow in a porous medium under the assumption of a compressible pore fluid but an incompressible soil. They found that the inclusion of pore fluid compressibility in the analysis of wave-induced pore pressures in a porous soil significantly altered the vertical seepage forces acting on the soil.

Yamamoto et al. (1978) have developed a quasi-static model of a poro-elastic sea bed using the equations developed by Biot (1941). They obtained solutions which, when best fit to laboratory data of pore pressure, showed reasonable

* Professor, Director of Institute of Hydroengineering, 80-288 Gdańsk, Poland.

** Research Assistant, Institute of Hydroengineering, 80-288 Gdańsk, Poland

for both magnitude and phase. Mei and Foda (1980) have shown that the boundary layer approximation well known in fluid dynamics, greatly facilitates the solution of Biot's equations for a variety of boundary conditions.

However, besides the numerous theoretical solutions, the published laboratory and field data are very scarce. Dunlap et al. (1978), Bennett and Faris (1979), and Cross et al. (1979) have presented the results of the experiments on the pore pressure generation in the sediments of Mississippi and coastal zone of Pacific. However, they are mainly related to the long-term changes. The relation of the observed pressure to the surface oscillations was not considered. The major objective of the present study is to describe the field measurement projects, i.e. LUBIATOWO 79 and LUBIATOWO 86 which were aimed at studying pore pressure behaviour in natural sand bed in the coastal zone of the Baltic Sea. The pore pressure measuring system is described and experimental results are compared with results of various analytical approaches.

2. Field experiments

2.1. Scope of the work

The field experiments were carried out at the Coastal Research Station in Lubiatowo (Poland) in the Southern Baltic (water depth $h \approx 6 \div 7$ m).

A set of over one hundred records were taken for various wave conditions at one profile. Simultaneous measurements of the sea surface oscillations, water pressures at two points in the water layer and pore pressures at four points in the soil layer were carried out (Fig. 2.1).

2.2. Porous layer characteristics

According to the geological information in the vicinity of the point of measurements, the thickness of the rather uniform sand is equal to ~ 6.5 m. The soil is of fine-grained type ($D_{10} = 0.135 \cdot 10^{-3}$ m, $D_{20} = 0.135 \cdot 10^{-3}$ m, $D_{60} = 0.150 \cdot 10^{-3}$ m, $D_{90} = 0.180 \cdot 10^{-3}$ m). Because the uniformity coefficient is less than 6 and the contents of the fraction $\leq 0.074 \cdot 10^{-3}$ m is less than 5%, the fine-grained sand can be classified as a poorly graded and fairly clean.

The density of soil or the porosity was not measured "in situ". Thus, only some estimation can be made. For very dense packing the porosity is about 26%, while for very loose it is about 47%. The large forces which were needed to push the pore pressure gauge indicated a rather dense packing of the sand at the measuring profile. Therefore, the porosity of sand is likely to be in the range 30 \div 40%.

Moreover, the experimental data on the permeability of the bed material were lacking. Thus, we adopted an empirical formulae to estimate the permeability from the grain-size distribution characteristics. The conclusion from these estimates is that the permeability coefficient is in the range of $10^{-5} \div 10^{-4}$ m/s.

Fig. 2.1. Measurement gauges lay-out

2.3 Instrumentation and measurements

All sensors were arranged in one profile and the measurement signals were transferred by cables to the Station building on shore. Due to access convenience, the gauges were attached to a framework fixed to the sheet-pile section of the platform.

The data were recorded in the real time in digital form. The system of transmission and acquisition of data consists of the modules of PCM transmitter and receiver, Camac system, microcomputer BIZON 580, PC computer and analog and digital recorder. The technical description of the instrumentation and transmission modules can be found elsewhere (Massel and Moshagen, 1980, Kaczmarek, 1987) and it will not be repeated here.

3. Statistical and spectral analysis of data

The surface waves observed in the coastal zone are the waves caused by the wind and then propagating under the restoring force of gravity. Under the assumption of the narrow-band spectrum and uniform distribution of the random phase, the surface ordinates a Gaussian distribution (Phillips, 1977). Such assumptions is expected to be realistic for small amplitude waves, specially in the deep water. However, the statistical analysis of the collected records indicates that the wave motion can be treated as nearly Gaussian process. Therefore:

$$p(\zeta) = p_n(\zeta) \left\{ 1 + \frac{\gamma_1}{3!} H_3 \left(\frac{\zeta}{\sigma_\zeta} \right) + \frac{\gamma_2}{4!} H_4 \left(\frac{\zeta}{\sigma_\zeta} \right) + \dots \right\} \quad (3.1)$$

where $p_n(\zeta)$ - Gaussian distribution, γ_1 - skewness, γ_2 - kurtosis, and $H(\cdot)$ - Hermitte polynomial. In fact γ_1 and γ_2 are both small values for the surface waves and the pore pressure. This is clearly demonstrated in Fig. 3.1. in

Fig. 3.1. Probability density distribution for surface waves and pore pressure.

which the corresponding probability density distributions are compared.

For the farther analysis we assume additionally that the system: surface waves - pore pressure is the linear system. Hence:

$$S_p(\omega) = |H(\omega)|^2 \cdot S_\zeta(\omega) \tag{3.2}$$

in which:

- $S_\zeta(\omega)$ - spectral density for the surface elevation,
- $S_p(\omega)$ - spectral density for the pore pressure, and
- $H(\omega)$ - transfer function.

As the empirical spectral density functions are known, the transfer function can be easily obtained. In the Figs. 3.2 and 3.3, the function $H_{p\zeta}(\omega)$ for the pore-pressure gauges at two points: $z = -1.0$ m (one meter below the bottom surface) and $z = -1.5$ m (one and half meter below the bottom surface). As should be expected, the function $H_{p\zeta}(\omega)$ is the decreasing function of the frequency. It should be noted, that during the measurements, the spectral peak frequency for the surface waves was in the interval of $0.80 \leq \omega_p \leq 1.50$ [rd/s], while the mean wave heights (\bar{H}) were of order $(0.50 \div 1.5$ m).

The calculations of the coherence function $\hat{\delta}_{p\zeta}^2$ (not shown here) indicate that the high values of the $\hat{\delta}_{p\zeta}^2$ function are related to the frequency band:

$$(0.6 \div 0.7) \leq \frac{\omega}{\omega_p} \leq (1.8 \div 2.) \tag{3.3}$$

Fig. 3.2. Transfer function $H_{p\zeta}(\omega)$ for pressure gauge at $z = -1.0$ m

Fig. 3.3. Transfer function $H_{pz}(\omega)$ for pressure gauge at $z = -1.5$ m

Outside that band the value of the coherence function is very small. Thus, the usefulness of the theoretical linear model for the pore-pressure decaying is restricted to the frequency band given above.

4. Validity of the potential theory approach

In order to simplify the analysis we assume that the regular long-crested wave with a frequency ω is propagating on the constant water depth. A homogeneous isotropic sediment is considered which has a constant thickness ($h_n - h$) on a rigid and impermeable bed rock h - water depth, h_n - depth of nonpermeable bed/.

The x axis is taken on the sea surface and the positive direction of the z axis is vertically upward.

We assume, that the soil skeleton obeys Hooke's law, i.e. the soil has linear, reversible isotropic, nonretarded mechanical properties. The exact solution for the pore-water pressure, the displacements, and the effective stresses in such elastic bed induced by water waves is based on the consolidation theory developed by Biot (1941). Since a complete description of the solution is given in the original paper, as well as in many text books (e.g. Verruijt, 1969), it will not be repeated here.

The general solution simplifies considerably in the special case, when $G/E'_w \rightarrow 0$, in which G - shear modulus of soil, i.e.

$$G = \frac{E_s}{2(1+\nu)} \quad (4.1)$$

where E - Young's modulus and ν - Poisson ratio.

The apparent bulk modulus of pore-water containing a some amount of air (E'_w) is related to the true bulk modulus of elasticity of water ($E_w = 2.3 \cdot 10^9$ N/m²) by the relation:

$$\frac{1}{E'_w} = \frac{1}{E_w} - \frac{1-S_r}{P_o} \quad (4.2)$$

where S_r - the degree of saturation and P_o is the absolute pore-water pressure.

The condition $G/E'_w \rightarrow 0$ corresponds to the soil completely saturated with pore-water which does not contain gas. Since the value of G for the fine sand as in LUBIATOWO experiments is about $10^7 \div 10^8$ N/m², the stiffness ratio, G/E'_w becomes:

$$G/E'_w \approx 10^{-2} \div 10^{-1} \quad (4.3)$$

The general solution of the boundary value problem under the condition $G/E'_w \rightarrow 0$ yields (Yamamoto et al., 1978; Massel, 1981):

$$\nabla^2 p = 0 \quad (4.4)$$

and

$$p \approx \cosh k(z+h_n), \quad (4.5)$$

in which k - wave number related to the frequency ω by the classical dispersion relation.

The result (4.4) is the same as that obtained by Massel (1976) (see also Putnam, 1949, Reid and Kajiura, 1957) who assumed that the soil is rigid and water is incompressible (the potential solution). The pressure attenuation for this case is small and independent of the permeability of the soil. From the theory given in Massel' (1976) paper, the following transfer function can be deduced:

$$H_{p\zeta}(\omega) = \frac{\cosh k(z+h_n)}{\cosh k(h_n-h) \cdot \cosh kh} \quad (4.6)$$

when the pore-pressure is expressed in the water column. The solution (4.6) is shown in the Figs. 3.3 and 3.4 by the solid lines. They confirm the general agreement between theory and experiment; especially in the frequency band, in which the coherence function $\hat{f}^2 \geq 0.75$. Out of this range, for the low frequencies, the experimental transfer function is smaller than the theoretical one. Reason for such behaviour is not quite clear.

5. Others theoretical solutions

The solution of Biot's equations for the various boundary conditions is greatly facilitated by the boundary layer approximation introduced by Mei and Foda (1980).

In this approximation, two regions with different physical mechanisms are distinguished. In the interior of the soil the water and solid skeleton velocities are assumed to be of the same order. On the other hand, near the bottom surface, the drainage is much easier and relative fluid velocity is higher. The solution of the problem consists of the solution of the typical elasto-static problem and the boundary layer correction being appreciable only within this layer.

The results of the calculation, according Mei and Foda (1980) approximation, are shown in Figs. 3.3. and 3.4. by the dotted lines. The agreement with the experimental data is quite good.

It should be noted that the calculations using the full Yamamoto et al. (1978) solution for true G/E'_w value were carried out. The results of calculations are in complete agreement with those of the boundary layer approximation; therefore they are not shown in Figs. 3.3 and 3.4.

6. Conclusions

In recent years the understanding of the interaction of the wave motion and the porous sea and the ability to predict the pore-pressure has increased considerably. A lot of the theoretical solutions were obtained. They include the effects of the stiffness of porous medium and the bulk modulus of water elasticity on the pore pressure attenuation, displacements and stresses in the porous media. However, the field data are not numerous. In the paper, the two field experiments were reported. The pore pressure attenuation was measured at a few levels in the porous media under the wind waves action. The collected data were processed and the statistical and spectral characteristics were found. The comparison of the experimental data with the various theoretical solutions demonstrates that the boundary layer approximation and the full Yamamoto et al. (1978) solutions properly reflects the observed physical mechanisms. The potential theory only slightly overpredicts the experimental values. However, it should be noted that this conclusion is true for the soil conditions similar to that in LUBIATOWO experiments (fine-grained sand).

CHAPTER 76

PROBABILITY OF WAVE BREAKING IN THREE-DIMENSIONAL SEAS.

D. Mather, M.W.G. Snook, C.A. Greated, *
W.J. Easson,** and I.G. Bryden. ***

Introduction

Current guidance notes for the design of offshore or coastal structures to withstand breaking waves are based on the behaviour of long-crested, monochromatic waves. It has been acknowledged for some time that although useful for first approximations and in some cases conservative load estimation, the adoption of long-crested wave theories and design principles for a short-crested sea environment may be inappropriate.

Halliwell & Machen (1981) have shown that in shallow water, isolated breaking waves under short-crested conditions can occur with greater elevations and hence potentially greater destructive power than existing design codes predict. Similarly work by Easson & Greated (1984) has highlighted deficiencies in wave theories to predict particle velocities and accelerations within waves by direct non-contact measurement of these properties, the implications being that such theories may significantly underestimate the total wave loading encountered under breaking waves. These observations call into question our ability to predict accurately and so design to withstand wave breaking effects in short-crested environments.

This paper reviews some of the present approaches to the prediction of wave breaking or whitecapping occurrences and compares data

collected offshore with simulations conducted in wave basin facilities in Edinburgh, which illustrate that wave breaking can occur at wave steepnesses significantly below those which are commonly assumed to represent the onset of breaking implying that design procedures must recognise and allow for this.

Survey of Reported Studies

Several authors have investigated the statistical properties of wave breaking by the visual observation of sea or model sea conditions to characterise properties of breaking or whitecapping wave crests.

Holthuijsen & Herbers (1986) observed the occurrence of whitecaps at a wave recording buoy in open sea conditions off the Dutch coast, the situation being such as to effectively represent a deep sea environment. Concurrent with the wave data, a visual identification time history technique for identifying the occurrence of whitecaps at the buoy permitted their correlation with wave elevation. By this method, each wave crest between zero-downcrossings could be individually distinguished as a whitecap or an undisturbed, plain wave. Their work compared the marginal and joint probability distributions of a number of wave characteristics (height, period, steepness, etc.) for both wave types together with a brief look into breaking occurrences within wave groups and as a function of wind speed. Unfortunately, although directional measurements were made at the site by the buoy, the nature of the resulting wave spectra were not presented.

Certain of the present authors recently pursued a similar series of investigations under model conditions using a video time logging technique (Mather et.al. 1988) to identify the occurrence of whitecaps on the resulting time history and other wave crest instabilities which were judged to be breaking waves. Under these idealised conditions - free of the effects of wind input, non-stationary wave conditions and currents - it was shown that no single geometric property of directionally spread waves recorded by a conventional omni-directional probe, could be used to distinguish breaking from plain waves.

These appear to be the only experiments reported which visually identify the breaking of waves and correlate them to elevation time histories in a three-dimensional environment, that is to say other than in a wave flume.

Papers by Kjeldsen & Myrhaug (1980) and Kjeldsen et.al. (1981) have established a number of wave geometry properties determined from single point measurements which are useful first descriptions of individual waves. In addition to the conventional definition of Wave Steepness (see Appendix), they also define Crest Front and Rear Steepnesses, Horizontal and Vertical Crest Assymetries. They established the advantages to be gained from using an analysis based on the Zero-Downcrossings rather than Crest or Zero-Upcrossing Period, from the standpoint of physically representative parameters and visual interpretation. They justify their opinion that the joint probability density function of Crest Front Steepness and Wave Height (evaluated between zero-downcrossings i.e. Crest to Preceding Trough) provides the most relevant characteristic for the useful forecasting of breaking waves (at high values of each property) but no guidance is given as to the quantitative regression line useful for this purpose.

Snyder and Kennedy (1983) investigated the probability of occurrence of whitecapping over an area at a fixed instant of time as distinct from other authors who considered temporal characteristics at discrete points. They argue the virtues of a variety of plausible wave and sea-surface characteristics which may potentially influence the occurrence of wave breaking. They assume that a single property may be adopted to form the basis of their theory and suggest on heuristic grounds that this must be a scalar quantity and exhibit relative maximum values only at wave crests. This leads to the identification of wave elevation, vertical surface acceleration and surface curvature as candidate properties. The use of elevation as an identifier is readily dismissed since breaking can be observed over a range of wave heights, just as some of the largest waves do not necessarily break. The argument used to dismiss the adoption of surface curvature is that of the practical difficulties to be encountered in quantitative description, analytical treatment and especially its measurement. Such problems of description and analysis stages are not insurmountable as work by Longuet-Higgins (1962) and Glazman (1985) demonstrates, whilst those of measurement do not seem to have been addressed in recent years in the context of water waves, despite the advances in topographic and remote-sensing methods.

X-Band microwave backscatter experiments by Kwoh & Lake (1984) operating with wavelengths of approximately 3cm, reported that backscattering events occurred in discrete bursts which were highly correlated with wave breaking events, contributions to these signals coming from the "background waveform" (the dominant source) and parasitic capillaries. Experimenting with a scanning laser-slope gauge they point out that scattering begins slightly before breaking under relatively smooth surface conditions, whereas conventional microwave backscatter detection relies on Bragg-Wave size surface roughness and that at peak response time the only high frequency feature in their tests are small radii wave crests implying that this small scale curvature may be a causal property of wave breaking. Srokosz (1988) however has pointed out that turbulence behind a breaking wave also leads to locally high curvatures and thus cannot reliably be applied as a characteristic, prerequisite to breaking.

The remaining identifier, that of vertical component surface acceleration, has so far seemed to yield the most promising identification results both in experiments (Snyder et.al. 1986) and theoretically [Longuet-Higgins 1969, Ochi & Tsai 1983, Srokosz 1984, Tung & Huang 1987, Huang et.al. 1986).

Huang et.al. (1986) developed an analytical description of whitecap coverage using the acceleration threshold criterion applied to probabilistic expressions of wave crest amplitude. As with other theories, they apply the restriction that wave breaking only occurs at wave crests in their model and so do not generalise the total coverage to include the effect of entrained foaming water which can be distinguished visually. The model is based on the Wallops spectrum (Huang et.al. 1981), containing the influence of the wind frictional velocity u_* , but the method could easily be applied to the more widely adopted Pierson-Moskowitz or JONSWAP system. In the work of Snyder et.al. the probabilistic description was obtained without adopting the (empirical) u_* and so is to be preferred as an analytic predictive tool although the empirical relationship in the Huang & Long model is probably no less valid and indeed may be preferred for its relative simplicity.

The work of Ochi & Tsai (1983) was one of the earliest to develop a probabilistic function for wave breaking occurrences, basing their efforts on the need to establish a more reliable statistical relationship between wave height and wave period, of those waves which would break. Their Figure 3 illustrates the difficulty in applying a single numerical relationship between these properties either as an average or an upper limiting criteria.

Model Simulation of Sea States

The Fluid Dynamics Unit at Edinburgh University has obtained wave data in the form of elevation plus two subsurface particle velocity components from a Southern North Sea platform site.

To extract the requisite spectral information from these records, the "Extended" Maximum Likelihood Method, due to Isobe et.al. (1984) was implemented. Sample resulting omni-directional point spectra of wave elevation and particle velocities together with the directionally spread variation of elevation spectra are shown in Figure 1. The growth in the spectral peak and its spread to lower frequencies as the storm developed was clearly visible when comparing successive sample spectra.

To investigate the probabilistic properties of wave breaking in the sea states computed from the site data, wave basin reproduction of these results was undertaken in the Edinburgh University Wide Wave Basin. This facility is described elsewhere [Salter, 1981] but briefly occupies a working area of 23m x 5m with 1.2m depth and with eighty, 0.3m width wavemakers occupying one long side. The wave generation system currently implemented is the "mixed frequency snake" summation of wavefronts permitting specification of the reproduced seas' RMS amplitude and discrete spectral form together with a discrete comb type directional spreading function.

The task of evaluating the directional wave spectrum in the wave basin poses the same problems of the same task at full size. In our experiments, the same analysis technique (the EMLM) was used as for determining the site directional spectrum, except that rather than elevation / velocity component combinations of data being analysed, it was decided to construct and use an array of conventional fixed wave probes. Seven probes were used and arranged as two regular, common-axis Mercedes-Benz style stars each of differing arm radius. This arrangement is more valuable in situations where the principal wave direction is unknown rather than for our application in a wave basin of known direction but the experience gained will, we feel, be of value when more fully assessing the analysis procedure at a later date.

Based upon visual inspection of the site spectra, we chose to attempt our simulations with the peak enhanced JONSWAP spectral form combined with the Cosine-power directional spreading function over a restricted range of angular values considered appropriate for modelling purposes ($\pm 45^\circ$) and beyond which the site data fell off to less than three percent of the peak value. The success of the simulations hinges on finding suitable parameters of the existing formulations, to match in a least squares way, the model form to the site results (Figures 2,3).

For the purposes of simulation this approach is not ideal, and the

Wave Elevation Parameterised Spectral Spreading

method proposed by Bryden & Greated (1984) in which white noise is passed through a digital filter offers realistic advantages. The filter used for wavemaker control can be formed to directly match the measured spectral output of the site data and so overcome the effects of mis-match between the real data and parameterised form. In so doing the greater influence of high-frequency components on wave breaking effects can be more reliably investigated below the upper limits of frequency reproduction possible with flexible-fronted wavemakers. The parameterised spectral forms invariably concentrate their modelling accuracy at the spectral peak and over the average rate of decay beyond that, without accounting for subtle variations which may occur - and were readily distinguishable in the spectra we evaluated throughout the storm - in the tail of the spectrum. This method is implemented in the Heriot-Watt University wave basin facility, but unfortunately this task was committed to other work at the scheduled time for testing. The Edinburgh Wide Wave Tank was however available and although not geared to White Noise Filtering wave generation, the reproduction of the parameterised spectra was well within its' capabilities.

The JONSWAP spectral form may represent a developing and developed sea-state by virtue of the peak enhancement factor (γ). In order to match the parameterisation to the measured spectra, the following justifications were adopted.....

- Peak frequencies will be the same $\omega_{0J} = \omega_0$
- Range of frequencies must match $\omega_{maxJ} = \omega_{max}$
- Total power in the spectrum must match $\int S_J(\omega)d\omega = \int S(\omega)d\omega$
- Peak spectral energies must be the same $S_J(\omega_0) = S(\omega_0)$

The parameterised spreading function was based solely on the measured spreading at the peak frequency (ω_0) and was not evaluated as a function of frequency so reducing the amount of computation necessary,

Least squares fitting of each parameterisation (frequency and direction) was adopted to optimise the spreading parameter (s) about the principal direction and for matching the third and fourth of the above frequency spectra constraints.

The original scope of the experimentation was to investigate the probability of wave breaking at an early stage of storm development (swell conditions) and then at the height of the same storm for which data was available, together with the effect of introducing or ignoring any directionality. As our experiments progressed it became clear that the record selected to represent the swell condition was not going to yield any significant breaking wave results as the physical size of the model sea was too small for reliable visual breaker identification in addition to the more implicit reason that wave breaking is generally to be associated with local rather than distant sea state generation. The number of breaking waves which did occur - even in an extended length test - were so few that there was too low a level of confidence in the results to yield an adequate statistic. As a consequence of the tests were re-defined to examine the effect on the breaking wave statistic of an increase in the energy content of the evaluated spectral form at the peak of the storm.

Four situations were reproduced from the parameterisations of available offshore wave spectral data. The first reproduced the omni-directional spectrum in a uni-directional (monochromatic) form, as is common practise, whilst the second introduced spreading according to the Cosine-power function suitably scaled to maintain the constant total power of the spectrum. The third and fourth tests used the same spectral form, peak frequency and frequency range but with an increase in the area under the spectral curve corresponding to a rise in the RMS waveheight of 40% based on a Rayleigh distribution. The technique adopted for identifying the geometric properties of the individual breaking waves is described elsewhere [Mather et.al. (1988)] and briefly, relates the time locations of visually identified breaking waves (from a video replay), to the wave record obtained from the reference wave probe. In this way each breaking crest is "flagged" to allow further investigation of whatever geometric or temporal property may be of interest (e.g. steepness, crest asymmetry, etc.)

Test Results

Probability density function histograms of geometry properties for each of the lower energy sea-states are shown in Figures 4,5, overlaying in each case the probability density histograms of breaking waves and all waves (plain and breaking). The properties illustrated were chosen from consideration of the results of Kjeldsen et.al. (1981), which were those most promising readily computed geometric characteristics likely to distinguish breaking from non-breaking waves. Review of our results led us to conclude that for each of the properties evaluated, breaking waves could occur over their whole range of realisable values.

In many instances the low number of samples of breaking waves lead to seemingly spurious results detached from the main body of the probability distribution, for example in all instances of elevation. Also clear is that the highest waveheight, longest periods, highest elevations or greatest steepnesses that do occur do not always break. This characteristic is particularly unsettling in each case of wave steepness, where the steepest identified breaking waves only exist up to about 75% of the values attained by plain waves. This may be a consequence of the fact that a visually identified breaker has to possess some whitecap which may have formed some relatively long time (at model scales) before passing the wave elevation probe. As a result the elevation will have diminished and the corresponding steepness reduced. Plain waves may on the other hand retain their form all the way up to breaking and inspection of the scales for each wave steepness shows that no waves occurred above values of between 0.055, 0.060 in each seastate of differing average wave height and director spreading. The values obtained for wave steepness on an individual wave basin were all significantly below the maximum value limited by breaking proposed by Hallam et.al. (1978) of 0.142. Small numbers of plain (i.e. non-breaking) waves did approach this value but with so many waves, this number became sufficiently insignificant as not to be apparent on the histograms.

The same problem is encountered when plotting the joint probability distribution (contour plots, Figures 6,7) in that as a wave breaks, its elevation and thus waveheight is reduced so that identified individual wave breaking occurrences on these figures are shifted away from their values at the point of breaking to that noted in each case,

FIGURE 4 abc

FIGURE 4 de

FIGURE 5 abc

FIGURE 5 de

FIGURE 6

FIGURE 7

these being the values observed at the elevation probe.

Two interesting points of note arise when comparing the monochromatic and directionally spread plots in each case of RMS waveheight. The introduction of a directional spread eliminates the occurrences of outlying, extreme value combinations of waveheight and period over the observed test periods though this observation cannot necessarily be assumed to be true when considering extreme value occurrences. This appears to be accompanied in each case by a drift of values towards the regression line equivalent to the maximum wave steepness.

Conclusions

These tests lend support to earlier work by Holthuijsen & Herbers (1986) and Mather et.al. (1988) that in directional seas there seems to be no obvious relationship between the occurrence of visually identifiable breaking events and any of the geometrically defined wave characteristics in current use. Future work in this field at the University of Edinburgh is to concentrate on attempts to relate the probability of wave breaking to sea-state spectral characteristics and simulations of directionally spread sea surfaces.

Acknowledgement

The authors wish to acknowledge British Maritime Technology Ltd. for financial support under the CASE scheme for Mr. Mather and are grateful to British Gas plc for access to the offshore site data. Many thanks also to Professor Stephen Salter and Mr. David Skyner at the University of Edinburgh and Dr. Meric Srokosz at the Institute of Oceanographic Science, Wormley for assistance during different stages of the preparation of this paper.

CHAPTER 77

A NEW PARAMETER FOR WAVE BREAKING WITH OPPOSING CURRENT ON SLOPING SEA BED

Shigeki Sakai*
Ken-ichi Hirayama**
Hiroshi Saeki***

INTRODUCTION

Opposing currents affect the wave breaking processes. The condition of wave breaking caused by opposing currents in deep water is described by the ratio of the wave celerity to the velocity of the opposing current (Yu(1952)). For the wave breaking caused by the opposing currents in shallow water on a flat bed, the equation given by Miche(1951) for the breaking criteria without current remains available (Iwagaki et al.(1980)). However, it is the breaking of shoaling wave in the presence of opposing current on a uniform slope, which is of concern in this paper.

Sakai et al.(1981) showed that the wave breaking affected by opposing currents on a sloping sea bed is characterized by a normalized unit width discharge q^* , as well as an incident wave steepness H_o/L_o and a slope of sea bed S , where q^* is defined as $q^* = q/g^2 T^3$; q : a unit width discharge, g : the gravitational acceleration, T : a wave period. They proposed diagrams for the breaker height and the breaking depth as a function of these three parameters. The breaker index curves in their diagrams show the relationships between the breaker height (or the breaking depth) and q^* for waves with particular values of H_o/L_o and S , and it is much more convenient to give a general expression for the breaker indices for arbitrary conditions of q^* , H_o/L_o and S .

The purpose of this study is to formulate the effects of these parameters on wave breaking, based on the results of systematic experiments performed by the authors, and to derive an empirical and simplified expression for the breaker height and depth in the presence of opposing currents.

*** Dept. of Civil Eng., Hokkaido Univ., Kita-13, Nishi-8, Sapporo, 060 Japan

The original idea is to choose the ratios of the breaker height (or depth) with opposing currents to the breaker height (or depth) without currents, and to search for an individual functional relationship between the ratios and each parameter (q^* , H_0/L_0 and S). Then, with the help of statistical approaches, these relationships are reorganized into a more simple relationship between the ratios and a new parameter.

EXPERIMENTS

Experiments were conducted by using two wave channels, one of which is 26m long, 1m deep and 0.36m wide; the other is 24m long, 0.8m deep and 0.36m wide. These have the same systems of wave generation and of water circulation. The slopes of the bottom were 1/50, 1/30 and 1/15.

Data acquisition of wave profiles was started when the first wave was generated, and the wave height was measured using five wave profiles from the sixth to the tenth, in order to avoid the reflecting waves. An incident wave height and length were calculated with the linear theory for wave with uniform current. The breakpoint was defined as a point which has the highest wave height. Experimental conditions of the unit width discharge, the wave period and the incident wave height are shown in table 1, and the ranges of the normalized unit width discharge and the incident wave steepness on each sea bed slope are given in Appendix A.

Table 1 Experimental conditions

unit width discharge	q : 0.0 ~ 790.0 ($\text{cm}^3/\text{s}/\text{cm}$)
wave period	T : 0.83 ~ 2.40 (s)
incident wave height	H_0 : 1.1 ~ 24.0 (cm)

NEW PARAMETER

In the present study, the breaker height (or depth) in the presence of the opposing current is examined, as compare to the breaker height (or depth) in the absence of the current. In this approach, the breaker height (or depth) in the absence of the current is expected to be described as a function of the incident wave steepness and the sea bed slope. The results of the present experiments without currents give the relationships between the breaker height (or depth) and the incident wave steepness for each sea bed slope, as shown in Appendix B-1 and B-2. In stead of scattering of data, the average lines were obtained for each cases. In the following discussion these average lines will be used to estimate the breaker height (or depth) without current. In these figures, the breaker index curves proposed by Goda(1970) are also illustrated. The present results are consistent with Goda's curves.

The influence of opposing currents appears in the change of breaking depth more significantly than in that of breaker height, and the normalized unit width discharge q^* explains the effects of opposing currents on wave transformation(Sakai and Saeki(1984)). The first step is to examine the relationship between R_h and q^* , where R_h is the ratio of breaking depth with and without opposing currents. Figure 1 shows the relationships between R_h and q^* for given H_0/L_0 on the slope

1/30. Rh depends on q* linearly, and then the relationship is expressed by the regression line for each condition of Ho/Lo. Since the slopes of regression lines (SRL)h depend on Ho/Lo, the relationship between (SRL)h and Ho/Lo is examined. Figure 2 shows that (SRL)h is inversely proportional to Ho/Lo on a logarithmic scale in cases where Ho/Lo < 0.05. (SRL)h also depends on the slope of sea bed. As shown in Figure 3, (SRL)h is proportional to the slope of sea bed S on a logarithmic scale. Then, the slope of regression line (SRL)h is described as follows:

$$(SRL)h \propto (H_0/L_0)^{-a} \cdot S^b = ((H_0/L_0) \cdot S^{-c})^{-a} \quad (1)$$

Figure 1 Relationship between Rh and q* (S=1/30)

Figure 2 Effect of Ho/Lo on (SRL)h

To explain the combined effects of H_o/L_o and S on $(SRL)_h$, the optimum value of c was found to be between 0.11 and 0.76. Figure 4 shows the relationship between $(SRL)_h$ and the combined parameter of H_o/L_o and S , with $c=0.41$, which gives the highest coefficient of correlation. Using the slope of regression line in this figure, $(SRL)_h$ can be formulated as a function of H_o/L_o and S .

Figure 3 Effect of S on $(SRL)_h$

Figure 4 Combined effect of H_o/L_o and S on $(SRL)_h$, with $c=0.41$

The relationships between RH and q^* are illustrated in Figure 5, where RH means the ratio of breaker height with and without opposing currents. The slope of regression line (SRL)H was examined as to be related to H_0/L_0 and S. A similar relationship was also obtained as follows:

$$(SRL)_H \propto (H_0/L_0)^{-a'} \cdot S^{b'} = ((H_0/L_0) \cdot S^{-c'})^{-a'} \quad (2)$$

The optimum value of c' is between 0.14 and 0.65. Figure 6 gives (SRL)H expressed by the combined parameter of H_0/L_0 and S, with $c'=0.37$.

Figure 5 Relationship between RH and q^* ($S=1/30$)

Figure 6 Combined effect of H_0/L_0 and S on (SRL)H, with $c'=0.37$

For a given H_0/L_0 and S , both R_h and R_H are proportional to q^* on a normal scale (see Figures 1 and 5). If the product of q^* and $(SRL)h$ (or $(SRL)H$) is chosen as a parameter, the relationship between R_h (or R_H) and this parameter will be described by a single line. Since the range of optimum value of c overlaps with that of c' , and it will be more convenient to define a single parameter, a new parameter was defined for both R_h and R_H , as follows:

$$\epsilon = \begin{cases} \frac{q^*}{H_0/L_0} \sqrt[4]{S} & H_0/L_0 \leq 0.05 \\ \frac{q^*}{0.05} \sqrt[4]{S} & H_0/L_0 > 0.05 \end{cases} \quad (3)$$

For waves with H_0/L_0 larger than 0.05, H_0/L_0 is assumed to be 0.05, since Figure 2 shows that $(SRL)h$ is not inversely proportional to H_0/L_0 for such cases.

Using the proposed parameter, all data were rearranged into a relationship between the ratios and ϵ . Both ratios (R_h and R_H) depend on ϵ linearly as shown in Figure 7, and ϵ explains the combined effects of q^* , H_0/L_0 and S on the wave breaking on a uniform slope, fairly well. Consequently, from the regression lines in this figure, R_h and R_H are formulated as follows:

$$R_h = \begin{cases} 0.93 + 170\epsilon & \epsilon \geq 0.0004 \\ 1.0 & \epsilon < 0.0004 \end{cases} \quad (4)$$

$$R_H = \begin{cases} 0.96 + 30\epsilon & \epsilon \geq 0.0013 \\ 1.0 & \epsilon < 0.0013 \end{cases} \quad (5)$$

Figure 7 Expressions for R_h and R_H by ϵ

CONCLUSIONS

In the present study, the influences of opposing current on wave breaking were formulated as functions of a new parameter ϵ , which accounts for the combined effects of the unit width discharge, the incident wave steepness and the sea bed slope. These formulations give the ratios of the breaker height(or depth) with and without opposing currents. Several results have been reported for wave breaking without currents. For example, Goda(1970) proposed diagrams for the relationships between the ratio of the breaker height to the incident wave height and the incident wave steepness. For the breaking depth or the maximum breaker height in a given depth, Weggel(1972) described the ratio of water depth to wave height at breakpoint as a function of breaker height, incident wave length and sea bed slope. Goda(1975) also gave another expression derived from his diagrams. These formulations and diagrams have been widely used to predict the breaker height and depth without currents. The present formulations gives the breaker height(or depth) with opposing currents, by using the breaker height(or depth) without current predicted by the previous studies.

CHAPTER 78

WHAT IS THE SLOPE OF EQUILIBRIUM RANGE IN THE FREQUENCY SPECTRUM OF WIND WAVES?¹

Paul C. Liu²

Abstract An effort to empirically assess the slope of the equilibrium range in a wind-wave frequency spectrum with a large number of data recorded in the Great Lakes did not serve to clarify the uncertainty between a -4 or a -5 frequency exponent representation. The uncertainty is further compounded by indications that the slope is not necessarily unique, it tends to vary with wave momentum. For sufficiently well-developed wind waves the exponent appears to cluster between -3 and -4. For practical applications the f^{-4} equilibrium range is perhaps an effective approximation. What the correct slope is for the equilibrium range, or even whether or not a unique slope exists, remains elusive and has yet to be satisfactorily substantiated.

Introduction

The slope of the equilibrium range on the high frequency side of a wind-wave frequency spectrum has been subjected to continued uncertainty over the last 35 years. In the decade of 1950s, there were three separate spectral representations with slopes of -6, -7, and -5 for the high frequency side of the spectrum developed respectively by Neumann (1953), Darbyshire (1955), and Roll and Fischer (1956). Phillips (1958) resolved these differences by inferring that a range of frequencies on the high frequency side of the spectrum will be dynamically saturated between energy input and dissipation processes, independent of wind stress, and proportional to the -5th power of frequency based on dimensional considerations. Oceanographers and coastal engineers have adhered to this f^{-5} equilibrium range concept since then, as many observations appeared to substantiate it. Recent observations, however, show evidence that the frequency spectrum is actually proportional to f^{-4} on the high frequency side rather than the widely used f^{-5} . Phillips (1985) re-examined the processes of energy input from wind stress, wave breaking and wave-wave interactions and revised his earlier concept by concluding

1 GLERL Contribution NO. 629.

2 Oceanographer, NOAA/Great Lakes Environmental Research Laboratory, 2205 Commonwealth Blvd., Ann Arbor, Michigan 48105

theoretically that the frequency spectrum $S(f)$ is in fact proportional to $g u_* f^{-4}$, where u_* is the wind friction velocity, as Toba (1973) and others have found empirically. While the ocean-wave community has gradually accepted this new concept (e.g., Battjes et al., 1987), there are still measurements showing f^{-5} to be a good representation. So what is the slope of equilibrium range in the frequency spectrum of wind waves? In this paper this question is explored, using a large number of measured wind-wave spectra in the Great Lakes to make a detailed examination of the equilibrium range slope of a wave spectrum.

Data

Eight NOAA Data Buoy Center (NDBC) buoys are deployed in the Great Lakes (Figure 1) during the ice-free period of the year, providing measurements of air and surface water temperature, wind speed and direction at 5 m above the water surface, and surface wave frequency spectra. The data used here were recorded by the NDBC buoys during 1981-1986. The wave spectra were calculated with 24 degree of freedom and a 0.4 Hz high frequency cutoff, from 20 minutes of hourly accelerometer measurements. A detailed description of the NDBC buoy measurement system is given in Hamilton (1986). A comparison of wave measurements obtained from a NDBC buoy and a Waverider buoy is presented in Schwab and Liu (1985).

Figure 1. Location map of the eight NDBC buoys in the Great Lakes.

With the wind speed and the air and water temperatures given from the measurements, the wind friction velocity u_* used in this study was readily obtained using the formula for overwater roughness length by Charnock (1955) with the formulation of stability length by Businger et al. (1971), assuming a constant neutral drag coefficient of $1.6 \times$

10^{-3} . This method is basically similar to various other methods of estimating u_w as shown in Liu and Schwab (1987).

Results and Discussions

An episode of well-defined wave growth was examined first. The episode was recorded from the Northern Lake Michigan Buoy 45002 on November 23, 1984. As shown on the left hand side of Figure 2, the wind was blowing steadily from the southwest direction with wind speeds increasing continuously from 7 ms^{-1} to over 15 ms^{-1} . Because of the relatively calm conditions prior to the episode, the wave field developed steadily with significant wave height growing from less than 1 m to 4.5 m over a 19-hour interval. The wave spectra recorded during the episode are plotted on the right hand side of Figure 2. The pure wave growth is exhibited by the continuous shifting of the front faces at the low frequency side of the spectra toward lower frequencies. The high frequency side of the spectra bands together to signify the equilibrium range. To see the slope of the equilibrium range we draw a f^{-5} line and a f^{-4} line along the banded part of the spectra. It is clear that either of the two straight lines could be considered good representation of the equilibrium range. Thus we are not able to visually delineate precisely which one provides a better representation.

Figure 2. Wind vectors and wave spectra plots of a growing wave episode in Northern Lake Michigan.

Normalizations

Several normalization schemes for studying spectral representation are available in the literature. One, proposed by Toba (1973) simply normalizes the spectral density $\Phi(f)$ by the peak energy density $\Phi(f_p)$ and the frequency f by the peak energy frequency f_p . A scheme adopted in Liu (1971) and others uses the same frequency normalization, but nondimensionalizes the spectral density by a factor of $f_p E^{-1}$ where E is the total energy integrated from the spectrum. Another scheme normalizes the spectral parameters with wind friction velocity u_* and acceleration of gravity g to yield normalized density and frequency as $\Phi(f)g^2u_*^{-5}$ and fu_*g^{-1} respectively. Phillips (1985) and several other authors have used this u_* normalization. An application of these three normalizations to the November 23, 1984 episode is shown in Figure 3. In the graphs the -4 as well as -5 slope lines are also drawn for comparison. Again, as in the case of the dimensional spectral plots, it is difficult to distinguish the best representation for the equilibrium range.

Figure 3. An application of three different normalizations to the growing wave episode spectra; -4 and -5 slope lines are included for comparison.

A frequency spectrum with f^{-5} equilibrium range is generally represented by

$$\Phi(f) = \beta(2\pi)^{-4}g^2f^{-5} \tag{1}$$

on the high frequency side. If (1) is valid then the normalized spectral density $\Phi(f)(2\pi)^4f^5g^{-2}$ should be independent of frequency and approaching the value β at the high frequency side. Similarly a frequency spectrum with f^{-4} equilibrium range can be represented by

$$\Phi(f) = \alpha(2\pi)^{-3}gu_*f^{-4} \tag{2}$$

In order for (2) to be the correct representation, the parameter $\Phi(f)(2\pi)^3f^4(gu_*)^{-1}$ should also be independent of frequency and approaching the value α at the high frequency side.

Figure 4. Normalizing the growing wave episode spectra with frequency exponents of 3, 4, 5, and 6 respectively shown clockwise from the lower left.

Rather than confining the exponent to merely -4 or -5, the formulations (1) and (2) can be generalized to allow any exponent i by

$$\Phi(f) = \alpha_i(2\pi)^{-i+1}g^{i-3}u_*^{5-i}f^{-i} \tag{3}$$

and then expect the normalized parameter $\Phi(f)(2\pi)^{i-1}g^{-i+3}u_*^{-5+if^i}$ to be constant and independent of frequency at the high frequency side if a given i is the valid exponent. Figure 4 shows the normalizations deduced from (3) for the same November 23, 1984 episode for $i = 3, 4, 5,$ and 6 . The results are now clearly distinctive. Only the bundle of f^{-4} normalizations shows a reasonably constant trend at the high frequency side. Thus this episode of wave growth spectra emerged to support the f^{-4} formulation.

Yet another normalization scheme is given in Donelan *et al.* (1985), which averages the high frequency side of the spectral density between $1.5f_p$ and $3f_p$ and uses it to normalize the whole spectrum. This scheme avoids the use of u_* , but the results are essentially the same as those in Figure 4.

Figure 5. Wind vectors and wave spectra plots of a well-developed wave episode in Northern Lake Michigan.

An Episode of Well-Developed Waves

If all the field measurement could provide results that are similar to Figure 4, then the results would lead to evident conclusions. Expecting to show the universality of the f^{-4} equilibrium range sustained in Figure 4, another episode measured from the same Northern Lake Michigan buoy only 12 days earlier was selected. This was an episode of well-developed waves with winds blowing from the north at virtually constant wind speeds of 12 ms^{-1} over 30 hours. This wind field generated significant wave heights of 2 m to 2.8 m during the episode. As shown in Figure 5 all the spectra were banded together over all frequency components as expected for a fully-developed wave field. The same normalization deduced from (3) that led to Figure 4

is applied to this episode and presented in Figure 6. These results are also distinctive. The constant trend of the normalization at the high frequency side is displayed, however, by the f^{-3} normalization rather than the f^{-4} .

Figure 6. Normalizing the well-developed wave episode spectra with frequency exponents of 3, 4, 5, and 6 respectively shown clockwise from the lower left.

These two episodes as presented in Figures 4 and 6 are not typical. Rather these were ideal cases selected from a large amount of available data to provide definitive and consistent results. The results presented in Figures 4 and 6 are, however, clearly inconsistent.

An immediate question arises: Is this inconsistency due to instrumentation? This seems not to be the case, since both episodes were recorded by the same NDBC buoy 45002 during a time period the gauge was known to be working properly - and 45002 is one of the earliest and most persistently operating gauge in the Great Lakes. It is conceivable that the slope of equilibrium range in the wave spectra is not unique, and that the growing and well-developed waves may render different slopes.

Figure 7. Percentage distributions of fitted slopes at the high frequency side of normalized wave spectra with frequency exponents of 3, 4, 5, and 6.

Examining Large Data Set

To further explore the "non-unique" nature of the equilibrium range slope in the wind wave spectra, many more data of selected episodes had to be examined. To do this systematically we arbitrarily combined 40 days of data that had been measured during October and November of 1984 from each of the three buoys 45003, 45006, and 45007 yielding a sample data set covering a variety of field measurement conditions. Spectra with peak-energy frequency higher than 0.25 hz were eliminated, to ensure the data were mainly well-developed or sustained growth waves. It is not practical to present graphs similar to Figures 4 and 6 for over 2200 items of data, but the same normalizations given in Figures 4 and 6 were applied to the data set and subsequently a linear regression line was fitted to each normalized spectrum between the frequency range of $1.5f_p$ and $3f_p$. A valid f^{-1} representation would render mostly "near zero" slopes to signify a constant trend over the normalized equilibrium range. Figure 7 presents the percentage distributions of these slopes, analogous to the four graphs given in Figures 4 and 6. Note that even though the four figures in Figure 7 were obtained from four separate normalizations, they were in fact the same distribution sliding over

different slope abscissa. In general, both f^{-3} and f^{-4} normalizations provide the most near zero slopes. This is consistent with the different results obtained in Figures 4 and 6, and it appears that the equilibrium range slope may very well not be unique.

To this point, in the normalization with f^{-1} , the equilibrium range frequency exponent i has been set to be 3, 4, 5, or 6. Alternatively, this requirement can be relaxed by simply fitting a linear regression line between the $1.5f_p$ and $3f_p$ range to the original wave spectra. The slope of the fitted line which may or may not be an integer, denoted by the exponent n as in f^{-n} , thus represents the actual measured equilibrium range slope of the spectra. The resulting percentage distribution of these exponents obtained from applying this approach to the combined data set is shown in Figure 8. Again, there is no single prevalent exponent, but the larger percentages lie between exponents 3.5 and 5.5.

Figure 8. Percentage distribution of the exponents n obtained by fitting the high frequency side of the original wave spectra with a logarithmic line of the form f^{-n} .

All of these results are consistent in that they lack clear indications of the existence of a unique equilibrium range slope. The inconsistent results shown in Figures 4 and 6 can now be readily justified as being characteristic of the non-uniqueness of the equilibrium range slope.

Figure 9. Correlating frequency exponents n of the equilibrium range, as in f^{-n} , with peak-energy frequency f_p .

Figure 10. Correlating frequency exponents n of the equilibrium range, as in f^{-n} , with total energy E .

Correlating the Equilibrium Range Frequency Exponent

Having been generally established that the frequency exponent of equilibrium range is not unique in this extensive data set, it is of interest to examine briefly the variability of the exponent. Meaningful correlations are lacking between the exponent and commonly used nondimensional parameters; however, the exponent tends to correlate well with dimensional parameters. Figures 9, 10, and 11 show respectively the exponent's correlation with peak-energy frequency, total spectral energy, and wave momentum. Basically the figures show that the exponent, at early wave growth stage, exhibits a decreasing trend versus decreasing peak-energy frequency, increasing wave energy, and consequently, increasing wave momentum. At the stage of well-developed or fully-developed waves the exponent appears to be unchanging and eventually settled between the absolute values of 3 and 4.

Figure 11. Correlating frequency exponents n of the equilibrium range, as in f^{-n} , with wave momentum E/c_p .

The non-uniqueness of the equilibrium range slope have been recognized by other investigators previously. Spectral representations with non-predetermined frequency exponent have been proposed for the high frequency side of the spectrum. Huang *et al.* (1981) deduced that the exponent was a function of the significant wave slope. Barenblatt and Leykin (1981) showed that the exponent relates to $g/(f_p u_*^2)$. The present analyses, however, do not seem to support either of these earlier results.

Concluding Remarks

This study was originally expected to simply delineate the applicability of f^{-4} or f^{-5} representation for the equilibrium range of the wind wave spectra. Examining over 2200 well-developed storm wave spectra recorded in the Great Lakes has not resolved the uncertainty. There are well documented cases for f^{-4} , f^{-5} , f^{-3} , and others, but the data seem not to converge and lead to a unique frequency exponent. As most of the exponents lie in the -3.5 and -5.5 range and between -3 and -4 for the fully developed cases, a representation of f^{-4} is perhaps a useful approximation for practical applications. What the correct slope is for the equilibrium range, or even whether or not a unique slope emerges, remains elusive and has yet to be satisfactorily substantiated.

CHAPTER 79

SURF BEAT GENERATION ON A MILD-SLOPE BEACH

Hemming A. Schäffer¹ and Ib A. Svendsen²

ABSTRACT: Two dimensional generation of surf beats by incident wave groups is examined theoretically. An inhomogeneous wave equation describes the amplitude of the surf beat wave. The forcing function is the modulation of the radiation stress. The short waves are amplitude modulated both outside and inside the surf zone causing the long wave generation to continue right to the shore line. Resonant generation as shallow water is approached is included. The analytical solution is evaluated numerically and shows a highly complicated amplitude variation of the surf beat depending on the parameters of the problem.

1. INTRODUCTION

Field observations show that on mild slope beaches a significant amount of wave energy occurs at frequencies far below the peak frequency of the incoming sea waves. The existence of such long waves were first reported by Munk (1949) who also speculated that the components with period around 2 minutes were caused by variation in height of the surf and he coined the name "surf beats." Also Tucker (1950) found long waves of 1-5 minute period with a height that increase linearly with the height of the short period sea, and a time lag corresponding approximately to the time it would take for a wave group to reach the breaker zone or beach and for a long wave generated there to be reflected back to the observation point. Longuet-Higgins and Stewart (1962,64) suggested that while the short waves are destroyed by breaking, the set-down wave generated by and following the wave groups outside the surf zone as a forced wave is reflected at the beach and propagates seaward as a free wave.

Since the first recording, numerous observations have shown that the energy of surf beat can actually be very substantial and in some cases even exceed that of the high frequency wind waves (Wright et al., 1982) and the amplitudes at the shoreline can be comparable to that of wind waves (Guza & Thornton, 1982,85).

Although no final proof has been established, it seems widely accepted today that the surf beats are generated by mechanisms in the nearshore region and that they are associated with modulations of the amplitude of the short-period incoming waves. However, several possible ways in which energy can be transferred from the high

frequency wind waves to the surf beats have been considered with more or less decisive results. It is likely that several possible mechanisms can be active either separately or at the same time. Closely related to the question of generation is the nature of the long wave motion in the nearshore region. In particular, it has been discussed extensively whether the nearshore long wave motion is dominated by forced or free waves; by progressive or standing waves, and whether it consists of crossshore directed (essentially two-dimensional) waves or trapped edge waves, which are three dimensional reflection-refraction wave patterns.

The present work assumes that the surf beat can exist as a two-dimensional motion. It is inspired by the work of Symonds et al. (1982) who investigated a mechanism for generating two dimensional surf beat that had not been considered previously. That mechanism is based on the fact that waves initially of different height will break at different distances from the shore line and (more important) have a different height at breaking. The surf beats are generated by the variation which this breaking pattern causes in the total radiation stress in the region between the extreme seaward and shoreward positions of the breakpoint. The varying breakpoint generates a shoreward moving long wave with the frequency of the wave groups, and since the forcing takes place only in the breaker region the long wave is a free wave through the rest of the surf zone. At the shoreline this wave is fully reflected so that a standing long wave is formed in the surf. Outside the surf zone the reflected wave continues seaward as a progressive wave.

In the model of Symonds et al., the groupiness of the waves is totally destroyed at the breaking point which is why there is no surf beat generation in the actual surf zone. A saturation model with a constant wave height to water depth ratio is used for the waves in the surf zone.

In the work presented in the following, we allow the wave groups to be maintained all the way to the shoreline. Measurements as well as experiments with the surf zone model developed by Svendsen (1984) indicates that if there is a variation in wave height at the breaker point the waves will remain different through the surf zone. For simplicity, we model this by introducing a breaker height variation at a fixed breaking point. This will represent the other extreme relative to the situation studied by Symonds et al. Observations show that the true picture probably represents a combination of the two: a varying breakpoint with some groupiness left in the surf zone. A somewhat similar problem was studied by Foda & Mei (1981) using a multiple scale expansion and different assumptions about the relative magnitude of the wave components involved. Our result contains a resonant interaction which was also included in the analysis by Freilich & Guza (1984) although under different assumptions about the magnitude of the bottom slope.

2. DESCRIPTION OF MODEL CONDITIONS

Since the phenomena associated with wave groups are quite complicated it may be useful to give a more detailed description of the situation which is created mathematically in the following.

Fig. 1: Sketch of bottom topography and short wave variation considered.

Region III

The situation is depicted in Fig. 1. We consider a region of constant depth which could be a continental shelf, say, (region III in the figure). In the present study we simplify by letting the groupiness of the waves be caused by two regular incoming wave trains with slightly different wave number $k_0(1+\epsilon)$ and $k_0(1-\epsilon)$ the second with a much smaller amplitude than the first. This implies that the surf beat wave becomes a simple wave of constant period which allows us to seek analytical solutions to the problem. The basic equations used, however, can also be applied to the general case of a time varying wave height as in a train of irregular Stokes waves, but this would require a numerical solution.

In region III we assume a quasi-uniform state. The modulation of the waves causes a variation in radiation stress which generates a set down wave, and we assume that the length of the wave height modulation is much larger than the depth so that the set down wave is a long wave. This set down wave and its propagation into the shore region was neglected by Symonds et al. (1982).

Present in region III is also an outgoing long wave which represents the results of the transformations and reflections taking place in the nearshore region. The amplitude and phase of that wave is one of the unknowns of the problem.

Region III is primarily introduced to be able to establish well defined and reasonably simple seaward boundary conditions for the problem.

Region II

In region II the depth is decreasing sufficiently gently that we can assume local solutions for short and long wave components. Thus the short wave will be shoaling towards the breaking point x_B . During this process, however, the balance between the variation in radiation stress and set down wave is constantly changing which causes the forced set down wave to grow. As the short waves approach breaking their group velocity approaches that of the forced wave creating a state of almost resonance. We describe this dynamical process (in contrast to the equilibrium situation in region III) by a WKB approximation.

For most values of the governing parameters we find that in spite of the resonant interaction the energy transferred from the short wave

to the forced wave is relatively small, and we therefore omit in the present paper to take the effect of this energy flux into account in the development of the short waves. There is no principle difficulty though in extending the formulation to include this effect as well.

At the transition point x_0 between region III and II the solutions for the two regions are matched by requiring continuity in mass and momentum flux for the long wave solution. These conditions cause a partial reflection at x_0 of the set down waves, whereas it is assumed that no such reflection occurs for the short waves (either because of sufficiently deep water or because the transition between horizontal and sloping bottom actually takes place sufficiently smoothly to allow the short waves to adjust).

Region I

At x_B the short waves are assumed to break. Since there is a temporal variation in the height of the waves reaching this point, we have a time-varying breaker height at x_B . The dissipation of energy in the surf zone is proportional to H^3 and therefore, although the wave height variation will decrease shorewards, those waves that are highest at the (fixed) breakpoint will always remain the highest, etc. Thus this mechanism implies that the groupiness of waves remains present all the way to the shoreline. It also implies that the generation process responsible for the modification of the forced long wave continues through the surf zone.

Again we have chosen to use the simplest possible description of the processes involved. Thus a saturation model based on $a=\gamma h$, where h is the water depth, is used to describe the wave height variation in the surf zone of the short waves. Essentially the specification of wave height as a fraction of depth replaces solution of the energy equation for the short waves. Since the short wave height varies as the groups propagate shorewards, this means that the parameter γ is $\gamma(x,t)$.

The matching at x_B again requires continuity in the mass and momentum flux for the long wave motion. The abrupt shift in the rate of change of the radiation stress represents a source of difference at the two sides of the matching point.

At the shoreline the long wave is fully reflected and radiated seaward as a free wave. The background for this assumption is discussed below and involves some aspects that, although known from other areas of wave dynamics, do not seem to have been applied before to analyze the behavior of surf beats near the shoreline.

3. THE GOVERNING EQUATIONS

The governing equations for the surf beat are derived from the depth integrated and time averaged equations for waves and currents (see e.g. Phillips, 1977; Mei, 1983). In those equations the set-up/set-down will then correspond to the long wave surf beat and the time-varying current will represent the particle motion in that long wave. Since the equations are derived under the assumption that the current velocity is uniform over depth, their use implies that we assume the surf beat is everywhere a long wave (as already indicated). On the other hand, the equations contain all relevant non-linear terms in the current discharge and set-up (including the momentum flux due to the mass flux Q_S in the waves). Thus the description of the long wave component of the wave motion is actually equivalent to that given by the nonlinear shallow water equations.

The total water particle velocity u is split into

$$u = u_w + U \quad (3.1)$$

where U is the velocity in the current, u_w that of the oscillatory motion so that $\bar{u}_w = 0$ below wave trough level ($\bar{\quad}$ meaning average over a wave period).

The relevant equations are then the continuity equation

$$\frac{\partial b}{\partial t} + \frac{\partial \bar{Q}}{\partial x} = 0 \quad (3.2)$$

where b is the elevation of the mean water surface and

$$\bar{Q} = Q_c + Q_s \quad ; \quad Q_s = \overline{\int_{-h_0}^{\eta} u_w dx} \quad ; \quad Q_c = \int_{-h_0}^c U dz \quad (3.3)$$

η is the total surface elevation measured from a horizontal reference level. The equation of shore-normal (x) momentum is

$$\frac{\partial \bar{Q}}{\partial t} + \frac{\partial}{\partial x} \left[\frac{\bar{Q}^2}{h} + \frac{1}{\rho} S_{xx} \right] + gh \frac{\partial b}{\partial x} + \frac{\bar{\tau}_b}{\rho} = 0 \quad (3.4)$$

in which h is the local depth (including the long wave surface elevation), S_{xx} is the shore wave radiation stress and $\bar{\tau}_b$ the mean bottom shear stress (which we will neglect here).

Since we are particularly interested in the surface elevation b of the long waves we first eliminate \bar{Q} from the linear terms of (3.2) and (3.4) by cross differentiation. This yields

$$\frac{\partial^2 b}{\partial t^2} - \frac{\partial}{\partial x} \left[gh \frac{\partial b}{\partial x} \right] - \frac{\partial}{\partial x} \left[\frac{\bar{Q}^2}{h} + \frac{1}{\rho} S_{xx} \right] = 0 \quad (3.5)$$

It is assumed that the total motion of any point consists of a quasisteady regular wave on which we superimpose a small perturbation (the amplitude modulation) that varies in time. Thus all wave averaged quantities have the form

$$f(x, t) = f_0(x) + f_1(x, t) \quad (3.6)$$

In particular the depth h is

$$h(x, t) = h_0(x) + b_0(x) + b_1(x, t) \quad (3.7)$$

By assuming that there is a steady state basic solution of wave height variation it can be inferred that for this solution there is no net mass flux. Hence by continuity $Q_0 = 0$ and

$$\bar{Q}(x, t) = Q_1(x, t) \quad (3.8)$$

When these assumptions are substituted into (3.5) we get the following equation for b_1

$$\frac{\partial^2 b_1}{\partial t^2} - \frac{\partial}{\partial x} \left[g(h_0 + b_0) \frac{\partial b_1}{\partial x} + gb_1 \frac{\partial b_0}{\partial x} \right] - \frac{\partial^2 S_{xx,1}}{\partial x^2} = 0 \quad (3.9)$$

where $S_{xx,1}$ represents the variation in S_{xx} due to the wave height modulation for the short waves (vide (3.6)).

Finally, realizing that at most points $b_0 \ll h_0$ we neglect terms proportional to $b_0 b_1$ so that the governing equation for the surf beat amplitude b_1 becomes

$$\frac{\partial^2 b_1}{\partial t^2} - \frac{\partial}{\partial x} \left(gh_0 \frac{\partial b_1}{\partial x} \right) - \frac{1}{\rho} \frac{\partial^2 S_{xx,1}}{\partial x^2} \quad (3.10)$$

This is a wave equation with a forcing term which represents the effect the wave height modulation has on the slowly varying surf beat. It is the same equation that was used by Symonds et al. (1982) but only in the region of the breaker point variation. Chu & Mei (1970) and Mei & Benmoussa (1984) derive the same equation for 3D by a multiple scale expansion of slowly varying Stokes waves.

Following Mei & Benmoussa (1984) we let the short wave motion be composed of two waves with almost the same wave numbers

$$\begin{aligned} \eta_1 &= \frac{1}{2} a_1 \exp \left[i \int k_1 dx + \omega_1 t \right] + * \\ \eta_2 &= \frac{1}{2} \delta a_1 \exp \left[i \int k_2 dx + \omega_2 t \right] + * \end{aligned} \quad (3.11)$$

where * means complex conjugate.

In region III we have k_1 and k_2 constant and we define k_0 and ϵ so that

$$k_1 = k_0(1+\epsilon) \quad ; \quad k_2 = k_0(1-\epsilon) \quad \text{for } x > x_0 \quad (3.12)$$

The equivalent change in wave frequencies are given by the dispersion relation. We have

$$\omega_g = \frac{1}{2} (\omega_1 - \omega_2) \approx \frac{\partial \omega}{\partial k} \cdot \epsilon k_0 = c_{g0} \epsilon k_0 = \frac{c_{g0}}{c_0} \epsilon \omega_0 \quad \text{for } x > x_0 \quad (3.13)$$

where c_{g0} is the group velocity in region III for the wave with wave number k_0 and frequency ω_0 and $c_0 = \omega_0/k_0$. Equation (3.13) also defines ω_0 as approximately $(\omega_1 + \omega_2)/2$.

The total short wave motion $\eta = \eta_1 + \eta_2$ can then be written

$$\eta = \frac{1}{2} A \exp \left\{ i \left[\int k_0 dx + \omega_0 t \right] \right\} + * \quad (3.14)$$

where A is a complex amplitude. With

$$\Omega_0 = \frac{c_{g0}}{c_0} \omega_0 \quad , \quad K_0 = k_0 \cdot \frac{c_{g0}}{c_g} \quad (3.15)$$

we get

$$A = a_1 \left[\exp \left\{ i \epsilon \left[\int K_0 dx + \Omega_0 t \right] \right\} + \delta \exp \left\{ -i \epsilon \left[\int K_0 dx + \Omega_0 t \right] \right\} \right] \quad (3.16)$$

or

$$\left. \begin{aligned} A &= a_1 \left[e^{i\theta} + \delta e^{-i\theta} \right] \\ \text{where } \theta &= \epsilon \left[\int K_0 dx + \Omega_0 t \right] \end{aligned} \right\} \quad (3.17)$$

The radiation stress S_{xx} for the short waves is then given by

$$\frac{1}{\rho} S_{xx} = \frac{g|A|^2}{2} \left[\frac{2c_g}{c} - \frac{1}{2} \right] \quad (3.18)$$

If we therefore write S_{xx} according to (3.6) we see that

$$\frac{1}{\rho} S_{xx,0} = \frac{g}{2} a_1^2 (1+\delta^2) \left[\frac{2c_g}{c} - \frac{1}{2} \right] \quad (3.19)$$

$$\frac{1}{\rho} S_{xx,1} = g a_1^2 \delta \left[\frac{2c_g}{c_0} - \frac{1}{2} \right] \exp(2i\theta) \quad (3.20)$$

Inside the surf zone the more general expression applies:

$$\frac{1}{\rho} S_{xx} = g|A|^2 P \quad (3.21)$$

In the present context, however, we will, for simplicity, allow P to be approximated by $(2c_g/c_0 - 1/2)$ since this only changes the results quantitatively not qualitatively.

The variation of b_1 and $S_{xx,1}$ is described by

$$b_1 = b_a \exp(2i\epsilon\Omega_0 t) \quad (3.22)$$

$$S_{xx,1} = S_a \exp(2i\epsilon\Omega_0 t) \quad (3.23)$$

so that

$$S_a = a_1^2 \delta \rho g \left[\frac{2c_g}{c_0} - \frac{1}{2} \right] \exp\left(2i\epsilon \int K_0 dx\right) \quad (3.24)$$

which substituted into (3.10) yields

$$\frac{\partial}{\partial x} \left[h_0 \frac{\partial b_a}{\partial x} \right] + 4\epsilon^2 \frac{\Omega_0^2}{g} b_a = -\frac{1}{\rho g} \frac{\partial^2 S_a}{\partial x^2} \quad (3.25)$$

This is the equation we solve.

Variation of Carrier Wave Amplitude

The two wave components a_1 and $a_1\delta$ which together form the carrier wave will show a variation that in region II corresponds to a simple shoaling under conservation of energy flux. Thus in region II we have

$$a_1 = \left(\frac{c_g \infty}{c_g} \right)^{1/2} a_\infty \quad ; \quad a_\infty = a_1(h=\infty) \quad (3.26)$$

In the surf zone (region I) the wave heights actually ought to be determined by one of the surf zone models developed in recent years as e.g. Svendsen (1984). This implies solving the energy and momentum equations using realistic descriptions for the relevant wave properties such as radiation stress, energy flux, and energy dissipation. If we assume that the wave height modulation in the wave groups is moderate, the breaker type will be virtually the same for all waves. Except perhaps for violently plunging waves (for which we know very little) this means that if two waves initially have different heights at the breaker point, the highest will remain so throughout the surf zone. Essentially this further implies that some groupiness is conserved also beyond the breaker point. How much of the original wave height modulation that actually is maintained will depend on how the variation in wave height influences the position of

the breaker point, an effect we, as mentioned earlier, have neglected here by using a fixed breaking point.

The above mentioned groupiness would result also from the wave model by Svendsen (or other wave models based on solving the energy equation). For simplicity, however, we choose a simpler representation of this physical feature by using a modified saturation model. In the surf zone we let

$$|A| = \gamma h \quad (3.27)$$

where $\gamma^2 = \gamma_0^2 + \gamma_1^2 e^{2i\theta}$. Particularly for $|A|^2$ we get

$$\begin{aligned} |A|^2 &= |A_0|^2 + |A_1|^2 \\ &= \left(\gamma_0^2 + |\gamma_1|^2 \left(e^{2i\theta} + * \right) / 2 \right) h^2 \end{aligned} \quad (3.28)$$

The values of γ_0 and γ_1 are then according to the saturation hypothesis determined by the breaker heights of the waves. Since before breaking we have

$$|A|^2 = (a_{\infty}^2(1+\delta^2) + a_{\infty}^2\delta(e^{2i\theta} + *)) \frac{c_{g\infty}}{c_g} \quad (3.29)$$

we get

$$\gamma_0^2 = \frac{a_{\infty}^2(1+\delta^2)}{c_{gB}^2 h_B^2} c_{g\infty} \quad (3.30)$$

and

$$\gamma_1^2 = \frac{2a_{\infty}^2\delta}{c_{gB}^2 h_B^2} c_{g\infty} \quad (3.31)$$

where index ∞ refers to deep water, index B to the values at the breaking point.

4. MATCHING AND BOUNDARY CONDITIONS

To obtain a solution over the three regions described in Section 2, we need a boundary condition at the outer end of region III, matching conditions between II and III and between I and II, and a boundary condition at the shore line. Since (3.25) is a second order equation a total 2x3 conditions are required to establish the solutions in the three regions.

Seaward Radiation Condition

The seaward boundary condition is a radiation condition stating that there are no free waves propagating towards the shore, only the bounded (and known) set down wave.

Matching Conditions

At x_0 and x_B the propagation conditions change, which causes changes in the constants of the general solution. We ensure continuity at those points by requiring that

$$\begin{bmatrix} b_a \end{bmatrix}_{x_0^-}^{x_0^+} = 0 \quad ; \quad \begin{bmatrix} b_a \end{bmatrix}_{x_B^-}^{x_B^+} = 0 \quad (4.1a,b)$$

This corresponds to assuming continuity in mass flux across x_0 and x_B . Similarly, continuity in momentum flux can be obtained by applying (3.4) on the two sides of each matching point in combination with (4.1a,b). This yields

$$\left[\frac{\partial b_a}{\partial x} \right]_{x_0^-}^{x_0^+} = - \frac{1}{\rho g h(x_0)} \left[\frac{\partial S_a}{\partial x} \right]_{x_0^-}^{x_0^+} \quad (4.2a)$$

$$\left[\frac{\partial b_a}{\partial x} \right]_{x_B^-}^{x_B^+} = - \frac{1}{\rho g h_B} \left[\frac{\partial S_a}{\partial x} \right]_{x_B^-}^{x_B^+} \quad (4.2b)$$

These relations indicate that db_a/dx will show a discontinuity at the two matching points, of which the one at x_B is by far the most significant.

Boundary Condition at the Shore Line

The model assumes that the short waves are entirely destroyed by breaking. No similar mechanism, however, is available for the long forced wave which will approach the shore line with a finite amount of energy. The wave must therefore be fully reflected there.

It is worth noticing that near the shoreline we actually stress the assumptions underlying the solution, which are that the bottom slope is gentle (i.e., $\Lambda = h_x L/h$ remains small) and the amplitude to depth ratio γ_s is small. As $h \rightarrow 0$, however, wave length of the long wave will go to zero as $h^{1/2}$. Hence the slope parameter Λ will grow as $h^{-1/2}$ for a constant h_x . Similarly, the amplitude to depth ratio of the long wave does not remain small.

The growth of Λ and γ_s near the shoreline indicates that the motion is more appropriately described by the nonlinear shallow water equations. However, the basic equations (3.2) & (3.4), and therefore also (3.5), remain valid even under those conditions since no assumptions as to the magnitude of Λ or γ_s have been invoked at the derivation of those equations. As mentioned previously, (3.2) and (3.4) correspond to this approximation, so that, close to the shore those two equations represent the appropriate description. Further away from the shore the NLSW-equations can then be matched to the linear solution as e.g. the wave equation (see Carrier, 1966).

In the present case (3.10) is a linearized form of (3.5) since some approximations have been introduced to get from (3.5) to (3.10). Therefore (3.10) does not represent a proper approximation as $h \rightarrow 0$.

This also applies to the WKB approximation used to transform (3.10) to (3.25), since that approximation also requires $\Lambda \ll 0(1)$ corresponding to small changes in depth over a wave length. It does of course also require $\gamma_s \ll 1$.

For the time being we have chosen to disregard the problem and simply assume that the linearized equation (3.22) applies to the shoreline. The requirement of full reflection then corresponds to requiring that close to the shoreline the wave motion is a purely standing wave with zero net energy flux. Since this approach is in agreement with the actual physical situation it only means that the description is not accurate near the shoreline. At some distance this solution should be the same as if a more correct matching with the NLSW approximation had actually been made.

5. SOLUTION FOR THE SURF BEAT AMPLITUDE

The complete solution to the homogeneous version of (3.25) can be expressed in terms of two linearly independent Hankel functions representing two waves propagating shoreward and seaward respectively. The complete solution to the inhomogeneous equation (3.25) can then be found by the method of variation of parameters. In region I and II we get ($i = 1, 2$) the complex solution

$$b_{a,i} = \left[H_0^{(1)}(a\sqrt{x}) \left[-C_i^{(1)} + \int^x H_0^{(2)}(a\sqrt{x}) \frac{d^2 S_a}{dx^2} dx \right] - H_0^{(2)}(a\sqrt{x}) \left[C_i^{(2)} + \int^x H_0^{(1)}(a\sqrt{x}) \frac{d^2 S_a}{dx^2} dx \right] \right] \frac{i\pi}{2\rho g h_x} \quad (5.1)$$

where $a = 4\omega g / \sqrt{g h_x}$. In region III the solution is

$$b_{a,3} = C_3 e^{i2\omega g x / \sqrt{g h_0}} + b_{a,0} \quad (5.2)$$

where $b_{a,0}$ is the incoming, forced set-down wave, for which we have

$$b_{a,0} = -\frac{1}{\rho} \frac{S_a}{g h_0 - c_{g0}^2} \quad (5.3)$$

The five constants $C_{1,2}^{(1)}$, $C_{1,2}^{(2)}$ and C_3 are then determined by the four matching conditions and by the boundary condition at the shoreline.

The latter requires that the amplitude of the two wave components are the same and hence yields directly

$$C_1^{(1)} = C_1^{(2)} \quad (5.4)$$

The four other constants are found numerically by solution of the flow complex equations resulting from applying the matching equations. The details are left out here.

6. NUMERICAL RESULTS

After determining the equations for the integration constants in (5.1) (5.2) and (5.3) numerical results have been calculated by evaluating the $\partial^2 S_a / \partial x^2$ term by numerical differentiation and similarly the integrals by numerical quadrature.

The problem under study has a substantial number of independent parameters. Clearly the bottom slope h_x is a parameter, but since the bottom steepness that the waves actually "feel" depends on the waterdepth to wavelength ratio the relevant measure of the bottom slope can be shown from the solution to be $\Lambda = h_x L/h$ where L is the local wave length defined as cT . Λ is assumed to be small in order to allow the waves to adjust to the local depth as assumed in the basic equations. In the solution Λ occurs in connection with the matching process at h_0 and h_B which leads to the two parameters

$$\Lambda_0 = \frac{h_x L_0}{h_0} \quad \& \quad \Lambda_B = \frac{h_x L_B}{h_B} \quad (6.1)$$

The value of Λ_B is actually determined by the assumed breaker index γ .

Other (small) parameters are the ratio of group wave number to carrier wave number

$$\epsilon = (k_1 - k_2) / 2k_0 \quad (6.2)$$

and the steepness of the carrier wave system

$$\epsilon_s = a_m \omega_0^2/g \tag{6.3}$$

The small parameter

$$\delta = a_2/a_1 \tag{6.4}$$

describes the weakness of the amplitude modulation causing the wave groups. Hence the problem is characterized by a total of five (small) parameters. In addition the dimensionless carrier wave frequency $\omega_0^2 h/g$ is of course important for the carrier wave description and particularly the value of $\omega_0^2 h_0/g$ connects the scale of the bottom geometry (h_0) to the length scale of the waves (g/ω_0^2).

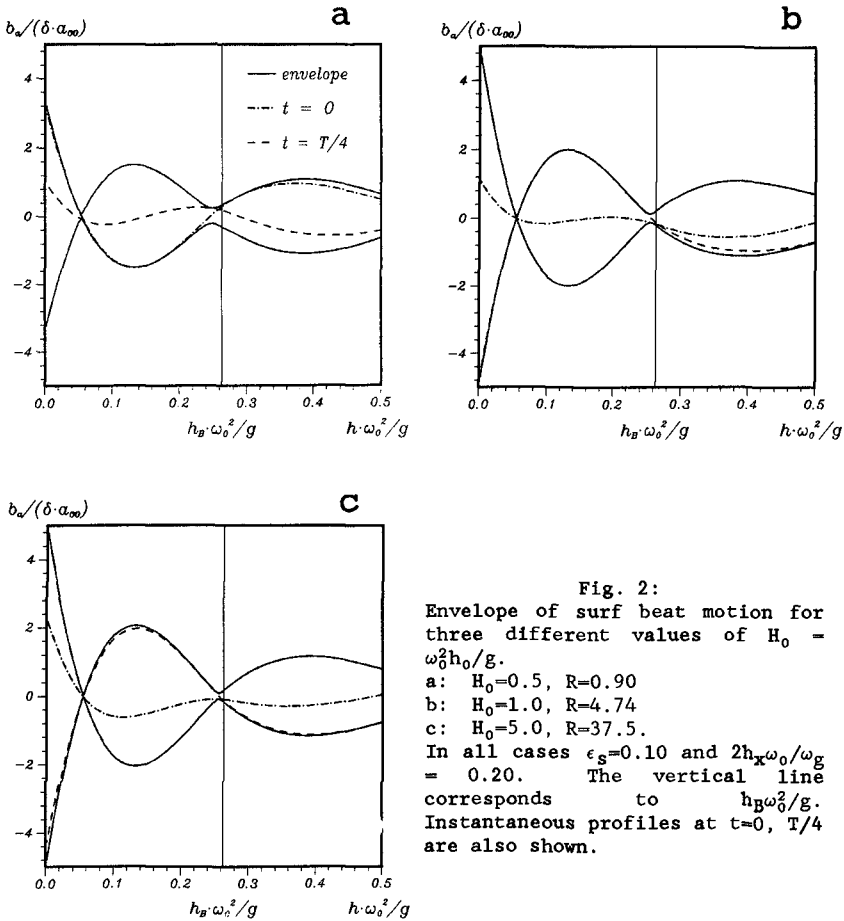

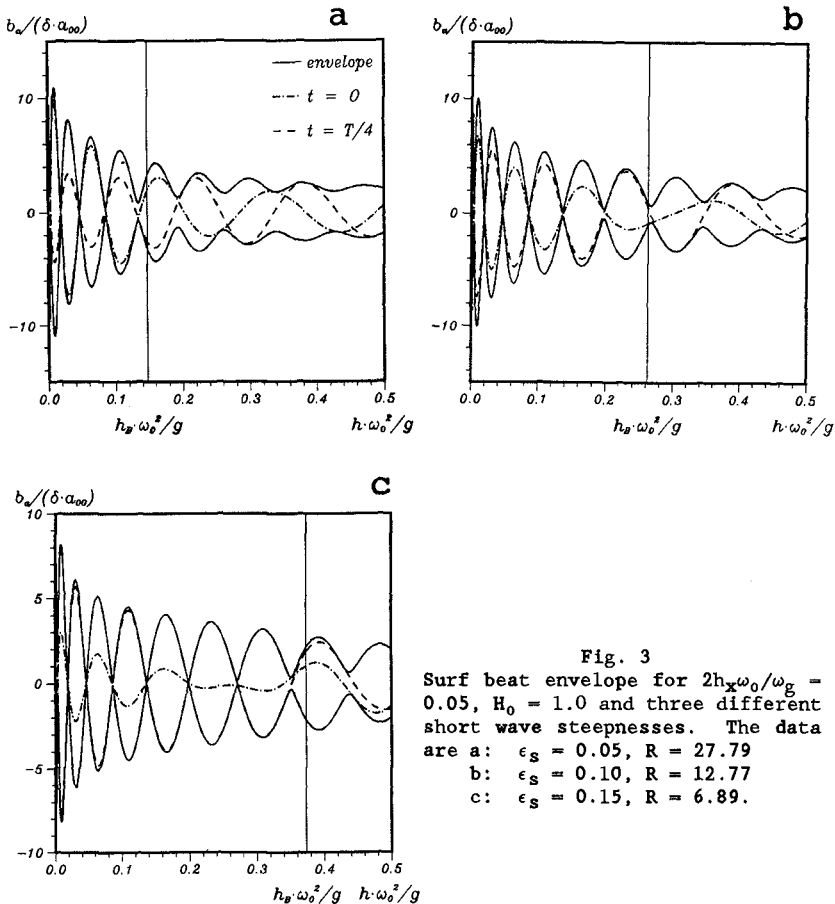

Fig. 2:
Envelope of surf beat motion for three different values of $H_0 = \omega_0^2 h_0/g$.
a: $H_0=0.5, R=0.90$
b: $H_0=1.0, R=4.74$
c: $H_0=5.0, R=37.5$.
In all cases $\epsilon_s=0.10$ and $2h_x \omega_0/\omega_g = 0.20$. The vertical line corresponds to $h_B \omega_0^2/g$. Instantaneous profiles at $t=0, T/4$ are also shown.

Fig. 2 shows the variation of the solution for the envelope b_a for a selection of parameter values. The three parts a, b & c corresponds to three different values of the parameter $H_0 = \omega_0^2 h_0/g$ (0.5, 1.0 and 5.0). In all three cases all other parameters have been kept

unchanged so that the three figures indicate the effect of increasing the depth h_0 in front of the slope (see Fig. 1) relative to the wave length of the carrier wave system.

Since it is difficult to compare the wave patterns as a whole we have chosen here to focus on the ratio between the amplitude of the wave propagating seawards in the constant region depth over the amplitude of the incoming set-down wave in the same region. This "reflection coefficient" R is a measure of how much the original set-down wave is amplified by energy transferred from the short wave system.

The variation of R we see in Fig. 2 is mainly due to the fact that the amplitude of the free (reflected) wave varies as $h_0^{-3/2}$ whereas the set-down wave decreases as h_0^{-1} as h_0 increases. Notice that for $H_0 = 1.0$ and 5.0 the figure does not show the whole slope region.

In Fig. 3 the total slope length has been kept constant and the position of the breaker point varied. The reflection coefficients of up to 28 show a significant amplification of the set down wave. On

the other hand, the value of R is biggest for the most narrow surf zone.

From those observations one might arrive at the conclusion that the surf beat generation primarily takes place on the slope seaward of the breaker point. This idea might be further supported by the fact that in the surf zone the minimum envelope amplitudes are very small as if the amplitude of the outgoing, reflected wave were nearly the same as the shoreward moving surf beat. (Clearly this becomes a better and better approximation the closer we get to the beach, as should be expected.)

To check this conjecture Fig. 4 shows numerical experiments with the same general data as in Fig. 3b (which is repeated in Fig. 4a for comparison). In Fig. 4b, however, we have artificially suppressed the surf beat generation inside the surf zone by letting the right hand side of (3.25) be zero in region I. Thus the long wave in the surf zone is now a standing free wave. We see there is a substantial reduction in the height of the surf beat generated as measured by the reflection coefficient, which drops from 12.77 to 8.58.

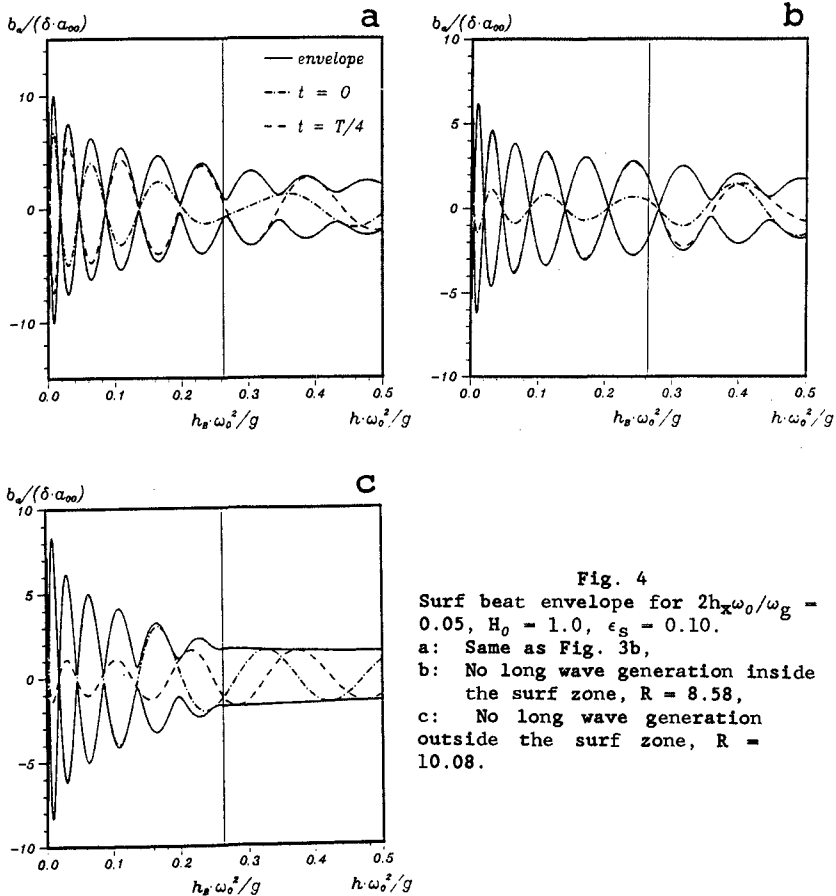

Fig. 4
Surf beat envelope for $2h_s \omega_0 / \omega_g = 0.05$, $H_0 = 1.0$, $\epsilon_S = 0.10$.
a: Same as Fig. 3b,
b: No long wave generation inside the surf zone, $R = 8.58$,
c: No long wave generation outside the surf zone, $R = 10.08$.

Similarly Fig. 4c shows a numerical experiment in which there is no long wave generation at all until in the surf zone. There the long wave motion outside the breaker point is a purely progressive wave moving seaward after having been reflected from the shoreline. This seaward oriented wave is now 10.8 times the set-down wave we would have had in the constant-depth region III had the generation been normal. In Fig. 5a-c the same type of experiment has been repeated for the same wave period and slope width but with the breaker point moved seaward by a change in carrier wave steepness. The picture is seen generally to be the same.

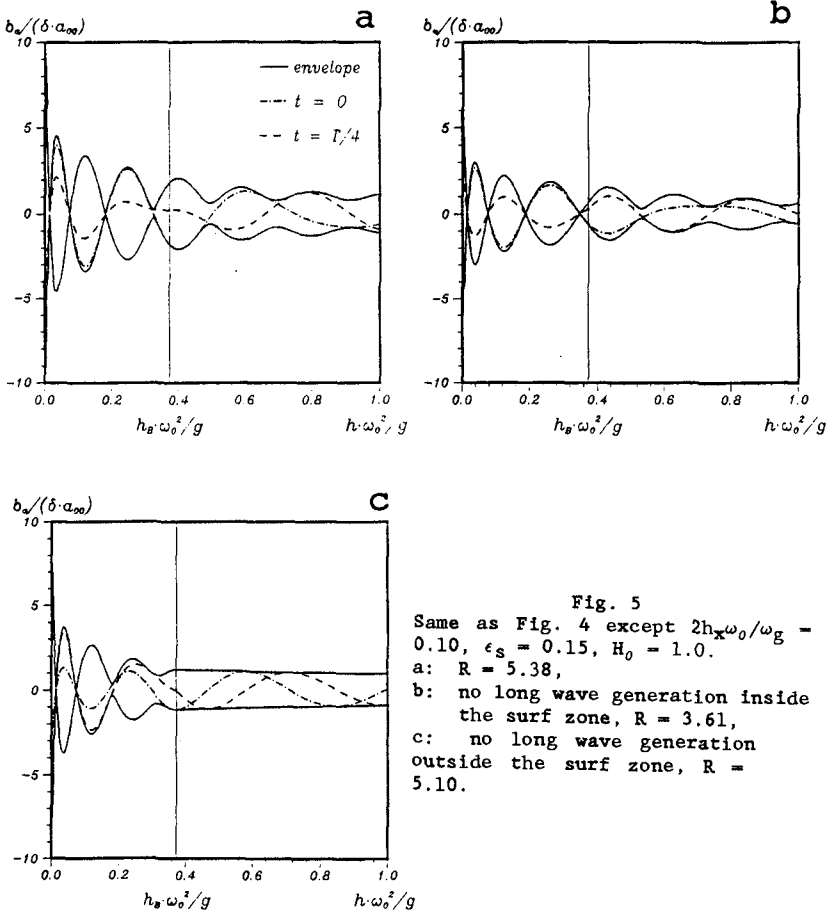

Fig. 5
 Same as Fig. 4 except $2h_x\omega_0/\omega_g = 0.10$, $\epsilon_s = 0.15$, $H_0 = 1.0$.
 a: $R = 5.38$,
 b: no long wave generation inside the surf zone, $R = 3.61$,
 c: no long wave generation outside the surf zone, $R = 5.10$.

As mentioned in section 2, as the waves move to shallower water the wave number of the wave groups approaches the wave number of the free wave solution to (3.25) and hence the generation process assumes the character of a resonant transfer of energy from the short waves to the shoreward moving long wave. This aspect of the process is equivalent to the resonant interaction first pointed out for water waves by Mei & Unluata (1972). Only here we meet a somewhat more complicated form where the wave number of the driving force instead of being constant

is slowly drifting towards the resonant wave number as the waves move shoreward. Although we have not yet studied the details of this situation it is undoubtedly the resonant nature of the process which is responsible for the large amplification indicated by the enormous reflection coefficients. On the other hand, since the nearly resonant interaction only takes place over a finite distance the amplitude of the surf beat of course remains finite.

CHAPTER 80

Solitary Wave Transmission through Porous Breakwaters

by

C. Vidal*, M. A. Losada*, R. Medina* and J. Rubio*

Abstract

A semi-empirical theory is formulated to predict wave reflection and transmission at a porous breakwater of rectangular cross section for normally incident solitary waves. The solution is based on the linearized form of the governing equations and on equivalent linearization of the friction loss in the porous structure.

Experimental results of transmission coefficients are presented for a large range of incident wave amplitudes, with several gravel sizes, water depths and breakwater geometries.

Experimental and theoretical results are compared and evaluated; the comparison shows satisfactory agreement for the transmission coefficient.

* Universidad de Cantabria. Spain.

Introduction

When a wave or surge reaches a rubble mound breakwater, it will be partly or totally reflected, depending on the permeability of the structure. Part of the flow may penetrate the porous barrier, and consequently the reflection is only partial. The incident wave energy is, in this way, split into reflected and transmitted. Reflection features determine the accessibility of the harbor trough its influence on the wave energy at the entrance, while transmission characteristics assess the effectiveness of the breakwater in protecting the harbor from the energy of incident waves.

An extensive literature has been reported to model the reflection-transmission features of a porous structure. The main approximations made in the literature are: the incident wave is harmonic and normal to the structure, the breakwater is a homogeneous isotropic medium governed by Darcy or Forchheimer type flow, the structure is of rectangular cross section. Sollit and Cross 1972, presented a summary of analytical approaches up to 1972. Madsen 1974 simplified the analysis presenting a linear long-wave model by assuming a Forchheimer type of flow and a linearized coefficient of friction. An extension of his model including trapezoidal cross section was given by Madsen and White, 1976. A statistical approach for random waves passing a perforated and porous breakwater was given by Massel and Mei, 1977. A generalization of Sollit and Cross work for multilayered structure with arbitrary cross section was presented by Sulisz, 1985. Damping of the incident and reflected waves due to bottom friction was considered in the long wave transmission through porous breakwater approach given by Scarlatos and Singh, 1987.

The long wave assumption made by several authors accounts for severe wave condition for most breakwaters. The governing equations for long waves in shallow water are the Boussinesq equations with the solitary wave as a typical solution. Theoretically, solitary waves have the advantage that, although non-linear, they can be described with two parameters: the wave height and the depth: experimentally they propagate with constant shape in constant depth and generally they can be separated from reflected waves. The objective of this study is to develop a semi-empirical model to the leading order for the motion of an incident solitary wave, the reflected wave and transmitted wave resulting from the presence of a normal rectangular cross section porous breakwater. This model will be checked with experimental tests. We assume first, that following ratios are small:

$$ak \ll 1 \quad kh \ll 1 \quad kb \ll 1 \quad O(b) \leq O(h)$$

in which a =wave amplitude, k =wave number, h =depth and b =breakwater width.

Following the procedure used by Mei, Liu and Ippen, 1974 for periodic long waves impinging on slotted or perforated breakwater and also used by Mei, 1983 for solitary waves climbing onto a shelf, three separate regions can be distinguished, within each of which different physical processes are dominant. In the evolution region, which is many wave lengths away from the breakwater, dispersion and nonlinearity are important and Boussinesq equations must be used. In the intermediate region roughly one wave length away from the breakwater, nonlinearity and dispersion are of second order in wave slope. In the neighborhood of the breakwater, where the typical distance is b , the loss friction effects are important but the apparent inertia due to local acceleration is not.

Theoretical formulation

Within the intermediate region, one-dimensional linearized equations are sufficient to the leading order:

$$\eta_x + h u_x = 0 \quad (1)$$

$$u_x + g \eta_x = 0 \quad (2)$$

the governing equations for the motion inside the porous rubble-mound are

$$n \eta_x + h u_x = 0 \quad (3)$$

$$(1/n) u_x + g \eta_x + (C_1 \mu / \rho d^n) u + (C_2 / d n^2) u^2 = 0 \quad (4)$$

where C_1 and C_2 account for the laminar and turbulent friction loss respectively and n is the porosity of the structure. The effect of friction loss is localized within $O(h)$ or $O(b)$ and can be represented as a boundary condition:

$$\eta_a - \eta_b = \frac{C_1 \mu}{d^n n g f} b u_b + \frac{C_2}{d g n^2} b u_b^2 \quad (5)$$

where subscripts $()_a$, $()_b$ indicate upstream and downstream respectively, and the apparent inertia (local acceleration) has been ignored in accordance with $kb \ll 1$.

As in the theory for perforated breakwater and for the scattering of a solitary wave at a sudden depth change and equivalent linear condition

$$\eta_a - \eta_b = c_a u_b \quad (6)$$

such that the total square error

$$e = \frac{C_1 \mu}{d^2 n g \rho} b u_b + \frac{C_2}{d g n^2} b u_b^2 - c_b u_b \quad (7)$$

is minimized over the wave period

$$\bar{e} = \int_{-\infty}^{\infty} e^2 dt$$

the minimum occurs when $\delta \bar{e} / \delta c_b = 0$. The optimum value of c_b is:

$$c_b = \frac{C_1 \mu}{d^2 n g \rho} b + \frac{C_2 b}{d g n^2} \frac{\bar{u}_b^2}{u_b^2} \quad (9)$$

we assume the incident wave is given by the solitary wave

$$\eta_1 = a_1 \operatorname{sech}^2 \lambda_1 (x - ct)$$

in which

$$\lambda_1 = (3 a_1 / 4 h^3)^{1/2}$$

$$c = (g h)^{1/2} (1 + a_1 / 2 h) \approx (g h)^{1/2}$$

Experimentally it has been observed that the transmitted and the reflected waves are similar in shape (sech^2 profiles) but not solitary waves, that is:

$$\eta_a = a_1 \operatorname{sech}^2 \lambda_1 (x - ct) + a_1 R \operatorname{sech}^2 \lambda_1 (x+ct) \quad (13)$$

$$\eta_b = a_1 T \operatorname{sech}^2 \lambda_1 (x - ct + \theta) \quad (14)$$

where R, T represent the reflection and transmission coefficients and θ is a phase shift. To the leading order, this phase shift is negligible when $kb \ll 1$. The corresponding horizontal velocities are:

$$u_a = (g a_1 / c) \left[\operatorname{sech}^2 \lambda_1 (x - ct) - R \operatorname{sech}^2 \lambda_1 (x+ct) \right] \quad (15)$$

$$u_b = (g a_1 T / c) \operatorname{sech}^2 \lambda_1 (x - ct) \quad (16)$$

We remark that the experimental assessment of constant λ_1 , can also be deduced from no phase shift and Eq. 1 in order to continuity to be satisfied for all t .

With these velocities, the coefficient c_w is:

$$c_w = \frac{C_1 \mu}{d^n n g \beta} b + \frac{C_2 b}{d n^n} \frac{a_1 T}{c} \quad (17)$$

Substituting Eq (13), (14), (16) into the boundary condition Eq (6), we obtain

$$1 + R = T \left(1 + \frac{c_w g}{c} \right) \quad (18)$$

Condition Eq 1 implies for the continuity of mass flux

$$1 - R = T \quad (19)$$

Combining Eq (18) with Eq (19), we obtain

$$T = \left[1 + \frac{c_w g}{2 c} \right]^{-1} \quad (20)$$

$$R = \left[\frac{c_w g}{2 c} \right] \left[1 + \frac{c_w g}{2 c} \right]^{-1} \quad (21)$$

the structure of Eq 20 also appears in the scattering of sinusoidal waves by perforated breakwater, in the scattering of solitary waves at a sudden depth change or in the scattering of sinusoidal waves by a porous breakwater.

Experimental Tests.

The tests were carried out in the 68 m long, 2 m wide, and 2 m deep wave channel of the water sciences Department of the University of Cantabria. In a length of 20 m, the flume has glass walls to allow visual observations. The incident solitary waves were generated with the procedure sketched by Goring, 1978. With this procedure, roughly one wave length away from the paddle the volume of water pushed by the paddle resembles a solitary wave.

As the solitary wave propagates on the horizontal smooth concrete bottom the frequency dispersion balances the non-linear effects and the waves remain stable without appreciable change. Only side wall and bottom friction cause a decrease of the wave amplitude. The measured profiles of the damped waves at the model test (47 m away from the paddle) are closely represented by the theoretical profile of Boussinesq, 1871. The agreement of both profiles is better on the upper 3/4 (Fig. 1).

* centimetres

The permeable structures tested had rectangular form and their characteristics are shown in table I. The tests were carried out with gravel of D₅₀=1.43, 2.43 cm and small cubic blocks of 3.15 cm side length. The measured porosities were n=0.44 for gravel and n=0.42 for cubes. The structures were 20 to 40 cm wide and water depth varied from 25 to 30 cm.

A wide range of incident wave amplitudes were tested so that the parameter a₁/h₀ range was 0.05 < a₁/h₀ < 0.5. Note that this last parameter (a₁/h₀=0.5) violates the small wave amplitude hypothesis.

The experimental arrangement is shown in figure 2. As the flume width was excessive for the test requirements it was divided longitudinally by a screen so that the model covered a width of only 60 cm. Within this new narrow channel all the measuring equipment was placed

as shown in figure 2. Upstream and downstream the model, two gauges were placed in order to measure the incident and the transmitted wave. Inside the permeable structure the pressure and water level were measured at several points depending on the structure width. A complete documentation of the experimental program is presented by Medina, 1988.

The experimental results of transmission coefficients for the different models are presented in table I. The transmission coefficient decreases when the structure width increases, the incident wave amplitude increases and the gravel size decreases. The influence of the water depth on the transmission coefficient is less important, and the transmitted wave amplitude decreases when the water depth decreases. Though the cubic block size is much larger than the gravel size, the transmission coefficient is slightly larger due to the lower porosity.

Comparison of theory and experiment.

For the experimental coefficients C_1 , C_2 , (Eq.17) we take the expressions given by Muskat, 1946, also used by Englund, 1953 and Madsen, 1974.

$$C_1 = \alpha (1-n)^2 / n$$

$$C_2 = \beta (1-n) / n$$

where $\alpha = 1092$, $\beta = 0.81$

The comparison of experimental transmission coefficient, T , and predicted transmission coefficient, T_t , for all the data given in table I is presented in fig. 3. The line $T_t=T$ is also drawn. As is evident from the comparison in fig. 3, the difference is small and the predicted transmission gives a reasonable representation of experimental data. Note that the experiments correspond to values of the parameter $0.05 < a_1/h < 0.5$ thus the agreement is good even for not too small wave amplitude ratio.

The influence on the transmission coefficient due to the grain size, incident wave amplitude, water depth and breakwater width is represented in figures 4-5 in which theoretical (lines) and measured (symbols) coefficients are drawn.

Figure 4 shows the influence of the breakwater width on the transmission; the transmission decreases when the width increases. Figure 5 shows the influence of the incident wave amplitude; the transmission decreases when the a_1/h ratio increases, we can also observe the agreement between predicted and measured coefficients for a wide range of the ratio a_1/h ($0.05 < a_1/h < 0.5$).

Fig. 3

Experimental versus Theoretical transmission

Summary and Conclusions

Based on a semi-empirical formulation, a simple solution for the reflection and transmission coefficients for a given incident solitary wave has been derived. This solution was based on the leading order of the governing equations and a linearized form of the friction loss in the porous structure. The linearization procedure was a slight modification of the Lorentz condition for sinusoidal waves. The coefficients depend on the geometry of the structure the incident wave amplitude, the water depth and on the properties of the porous medium (porosity and grain diameter).

Experimental results of transmission coefficients have been reported for a wide range of the involved parameters. These results have been compared with the predicted values showing a satisfactory agreement for the transmission coefficient.

CHAPTER 81

TIME-DEPENDENT WAVE SHEAR STRESS

By Suphat Vongvisessomjai¹, M.ASCE

ABSTRACT

A knowledge of bed shear stress induced by waves is required to understand dynamic processes of nearshore morphologies as a results of sediment transport. However, the information on the stress is still incomplete due to lack of measured data. The study analyzes the unsteady horizontally averaged shear stresses measured over mobile beds in a water tunnel. It is found from the analysis that the presence of the third and fifth harmonics in the shear stress is in good agreement with the measured concentration of suspended sediments.

INTRODUCTION

Magnitude and phase of bed shear stress induced by waves over mobile bed depend on characteristics of waves and wave induced ripples on the bed. The magnitude of bed shear stress can be computed from known wave friction factor over mobile bed, Grant and Madsen (1982) and Vongvisessomjai (1987). Lofquist (1986) provided experimental results of the time-dependent drags on naturally rippled sand beds tested in a water tunnel which were obtained from the measured difference between pressure gradients in the test section split longitudinally into two channels, one containing the sand bed and the other having a smooth metallic bottom. Two sands were used, with diameters 0.55 and 0.18 mm. The bottom stress, including skin friction and profile drag components was found to be a fairly complicated function of the phase and not proportional to the square of the simultaneous sinusoidal velocity far above the bed. Average values of the bottom stress and coefficient of energy dissipation were both typically an order to magnitude greater than for a flat surface roughened with fixed grains. The wave friction factors on mobile beds f_{ws} , computed from the coefficient of energy dissipation \bar{f}_1 of Lofquist (1986) with the conversion $f_{ws} = (3\pi/4) \bar{f}_1$, were found to have the same order of magnitudes as those obtained by Vongvisessomjai (1987).

The time-dependent wave shear stresses obtained by Lofquist (1986) are analyzed and quantified for the phases, and the obtained friction factors together with the earlier results are used to develop a new expression.

¹ Professor, Division of Water Resources Engrg., Asian Inst. of Tech., P.O. Box 2754, Bangkok 10501, Thailand.

METHODOLOGY

The velocity field over the self-formed 2 dimensional ripple of $h = \eta \cos(2\pi x/\lambda)$ can be expressed as a sum of the fundamental component ($n = 0$) and its higher harmonics ($n = 1, 2, 3...$) caused by the presences of eddies or turbulences generated from the interaction of the fundamental component and the ripples as

$$u(x,z,t) = \sum_n \epsilon^n u_n(x,z,t) \dots\dots\dots(1)$$

where $\epsilon =$ a small parameter.

The corresponding shear stresses along the ripple bed can be expressed as

$$\tau_o(x,t) = \sum_n \epsilon^n \tau_{on}(x,t) \dots\dots\dots(2)$$

where subscript o denotes the bed, $z = 0$.

These velocity field, shear stresses and eddies will cause sediment suspension in the form

$$c(x,z,t) = \bar{c}(x,z) + \sum_n \epsilon^n c_n(x,z,t) \dots\dots\dots(3)$$

These unsteady two dimensional velocity, the unsteady shear stress along the ripple and the suspended sediment concentration are too complicated to be measured and quantified. Only some measurements are presently available for horizontally averaged values of the above parameters which can be expressed respectively as

$$\bar{u}(z,t) = \frac{1}{\lambda} \int_0^\lambda u(x,z,t) dx = \sum_n \epsilon^n \bar{u}_n(z,t) \dots\dots\dots(4)$$

$$\bar{\tau}_o(t) = \frac{1}{\lambda} \int_0^\lambda \tau_o(x,t) dx = \sum_n \epsilon^n \bar{\tau}_{on}(t) \dots\dots\dots(5)$$

$$\bar{c}(z,t) = \bar{c}(z) + \sum_n \epsilon^n \bar{c}_n(z,t) \dots\dots\dots(6)$$

The following analysis is based on the approach of Lofquist (1986) in analyzing his experimental results. The freestream velocity of flow above the bed and beyond its effects is

$$u_\alpha = \left(\frac{2\pi a}{T} \right) \sin \left(\frac{2\pi t}{T} \right) = U \sin \theta \dots\dots\dots(7)$$

where t is the time T is the period and $2a$ is the orbital diameter of the water motion. Equation (7) defines the maximum velocity, U , and the phase, θ . The bed surface profile, assumed two dimensional and periodic with length λ , has elevation $h(x,\theta)$, where x is the horizontal coordinate. The average bottom stress is then defined by

$$\bar{\tau}_o(\theta) = \frac{1}{\lambda} \int_0^\lambda \left[\tau_h + (p_h - p_\alpha) \frac{\partial h}{\partial x} \right] dx \dots\dots\dots(8)$$

where τ_{t_1} is the local tangential stress on the bed, and $(P_h - P_a)$ is the difference between pressures at the bed surface and at any fixed elevation beyond the influence of the bed. Separate integrals for the two terms in the integrand would resolve $\tau_o(\theta)$ into components expressing the effects of tangential and normal stresses, the latter being a form drag. However, such a separation is generally impossible. A stress coefficient has been made dimensionless for bottom stress by dividing by ρU^2 , rather than by $\rho u_o^2(\theta)$, in order to keep it proportional to the bottom stress throughout the cycle where ρ is the density of water,

$$f(\theta) = \frac{2 \bar{\tau}_o(\theta)}{\rho U^2} = f_s(\theta) + f_n(\theta) \dots\dots\dots(9)$$

The dimensionless local tangential stress over the smooth boundary for laminar flow is

$$f_s(\theta) = \beta_4 \sin(\theta + \pi/4) \text{ where } \beta_4 = \sqrt{\frac{\nu}{a^2\omega}} \dots\dots\dots(10)$$

and the dimensionless normal stress is

$$f_n(\theta) = \beta_1 \bar{D}(\theta) \text{ where } \beta_1 = \frac{2H}{\rho LU^2} \dots\dots\dots(11)$$

in which $\omega = 2\pi/T$; H = height of pressure taps from bed; and L = distance between pressure taps.

The measured differential pressure $\bar{D}(\theta)$ is found to be the summation of the fundamental harmonic $D_1(\theta)$ and its higher odd harmonics as

$$\bar{D}(\theta) = D_1(\theta) + D_3(\theta) + D_5(\theta) + \dots \dots\dots(12)$$

It was found from the experiments that there existed a shift of the mean level of ripple bed from the initial bed of \bar{h} , a correction of $2\bar{h}/a = \beta_3$ is made to Eq. 9 as

$$f(\theta) = \beta_1 \bar{D}(\theta) - \beta_3 \cos \theta + \beta_4 \sin(\theta + \pi/4) \dots\dots\dots(13)$$

ANALYSIS AND RESULTS

Expressions of friction factor on fixed bed are first summarized for comparison with the obtained friction factor on mobile beds from this analysis. The friction factor can then be used to compute the magnitude of the maximum bed shear stress. The analysis of the phase of the shear stress is finally made.

Friction Factor of Fixed Bed.— Jonsson (1966) defined the wave friction factor $f_w = 2 \bar{\tau}_{om}/(\rho U^2)$ where subscript m denotes the maximum value and expressed it in terms of the relative smoothness of the bed $k_* = a/k_s$ as

$$\frac{1}{4\sqrt{f_w}} + \log \frac{1}{4\sqrt{f_w}} = -0.08 + \log k_* \dots\dots\dots(14)$$

The above expression was later confirmed by two additional sets of tests in a water tunnel by Jonsson and Carlsen (1976).

Kamphuis (1975) reanalyzed the measured values of the friction factors obtained by Riedel, Kamphuis and Brebner (1972) and proposed an expression for the friction factor also in terms of k_* as

$$\frac{1}{4\sqrt{f_w}} + \log \frac{1}{4\sqrt{f_w}} = -0.35 + \frac{4}{3} \log k_* \dots\dots\dots(15)$$

Grant and Madsen (1979) derived an expression of friction factor for combined waves and currents in fully rough turbulent flow. A relationship between f_w and k_* could be obtained for the limiting condition of a pure wave motion as

$$f_w = 0.08/[Ker^2 2(\zeta_c)^{1/2} + Kei^2 2(\zeta_o)^{1/2}] \text{ for } k_* > 1 \dots\dots\dots(16)$$

and $f_w = 0.23$ for $k_* < 1$; in which the dimensionless roughness length $\zeta_o = k_s/(30\ell)$; the characteristic length $\ell = 0.4 u_*/\omega$; the shear velocity $u_* = \sqrt{f_w} 2U$; Ker and Kei = Kelvin functions of zero order.

Vongvisessomjai's (1984) expression of wave friction factor

$$f_w = 0.287 k_*^{-2/3} \dots\dots\dots(17)$$

Friction Factor of Mobile Bed.- Grant and Madsen (1982) presented a model to predict the roughness in unsteady oscillatory flows over mobile beds using data of Carstens et al. (1969). The total roughness was the sum of the form drag component and the sediment transport component:

$$\frac{1}{k_*} = 2B \frac{\eta}{a} \frac{\eta}{\lambda} + 160(s+K) \frac{D}{a} \left[\left(\frac{\psi}{\psi_c} \right)^{1/2} - 0.7 \right]^2 \dots\dots\dots(18)$$

in which $K = 1/2$ for spherical sand; $\psi =$ Shields parameters; and $\psi_c =$ critical value of Shields parameter for initiation motion. Based on the law-of-the-wall, the expression of friction factor of the fixed bed, Eq. 16, was adopted for that of the mobile bed using k_* of Eq. 18.

Profiles of mean and unsteady concentration were derived by Vongvisessomjai (1986) from the mass conservation equation using the diffusion coefficient profile adapted from the eddy viscosity profile of Vongvisessomjai (1984) taking into account changes of the friction factor and boundary layer thickness in the presence of suspension. The theoretical profiles were expressed explicitly as functions of the friction factor, velocity and shear stress profile parameters, and the settling velocity of the sediment relative to the fluid velocity. The tabulated data available and the new experimental data of the mean concentration were used to fit the theoretical profile. The ratio of the friction factor f_{ws}/f_w obtained was then correlated to the densimetric sediment Froude number $Fd_* = U^2/[(s-1)gD]$ and the relative bed smoothness $a_* = a/D$ as

$$\frac{f_{ws}}{f_w} = 0.866 Fd_*^{-0.50} a_*^{0.17} \text{ for fine sand}$$

or

$$f_{ws} = 0.185 Fd_*^{-0.50} a_*^{0.17} \quad \text{for } f_w \dot{=} 0.214 \dots\dots\dots(19)$$

Vongvisessomjai (1987) based on his friction factors obtained from suspended sediment profile data and those of Carstens et al. (1969) expressed f_{ws} as function of Fd_* , a_* and $D_* = (s-1)gD^3/\nu^2$.

$$f_{ws} = 0.049 Fd_*^{-0.44} a_*^{0.21} D_*^{0.22} \dots\dots\dots(20)$$
